• class tf.bytes

Classes and functions for building TensorFlow graphs.

Core graph data structures

```
class tf.Graph
```

A TensorFlow computation, represented as a dataflow graph.

A Graph contains a set of Operation objects, which represent units of computation; and Tensor objects, which represent the units of data that flow between operations.

A default Graph is always registered, and accessible by

calling tf.get_default_graph(). To add an operation to the default graph, simply call one of the functions that defines a new Operation:

```
c = tf.constant(4.0)
assert c.graph is tf.get_default_graph()
```

Another typical usage involves the Graph.as_default () context manager, which overrides the current default graph for the lifetime of the context:

```
g = tf.Graph()
with g.as_default():
    # Define operations and tensors in `g`.
    c = tf.constant(30.0)
    assert c.graph is g
```

Important note: This class is not thread-safe for graph construction. All operations should be created from a single thread, or external synchronization must be provided. Unless otherwise specified, all methods are not thread-safe.

```
tf.Graph. init ()
```

Creates a new, empty Graph.

```
tf.Graph.as default()
```

Returns a context manager that makes this Graph the default graph.

This method should be used if you want to create multiple graphs in the same process. For convenience, a global default graph is provided, and all ops will be added to this graph if you do not create a new graph explicitly. Use this method the with keyword to specify that ops created within the scope of a block should be added to this graph.

The default graph is a property of the current thread. If you create a new thread, and wish to use the default graph in that thread, you must explicitly add a with g.as_default(): in that thread's function.

The following code examples are equivalent:

```
# 1. Using Graph.as_default():
g = tf.Graph()
with g.as_default():
    c = tf.constant(5.0)
    assert c.graph is g

# 2. Constructing and making default:
with tf.Graph().as_default() as g:
    c = tf.constant(5.0)
    assert c.graph is g
```

Returns:

A context manager for using this graph as the default graph.

```
tf.Graph.as_graph_def(from_version=None,
add shapes=False)
```

Returns a serialized GraphDef representation of this graph.

The serialized GraphDef can be imported into

another Graph (using import_graph_def()) or used with the C++ Session API.

This method is thread-safe.

Args:

- from_version: Optional. If this is set, returns a GraphDef containing
 only the nodes that were added to this graph since
 its version property had the given value.
- add_shapes: If true, adds an "_output_shapes" list attr to each node
 with the inferred shapes of each of its outputs.

Returns:

A GraphDef protocol buffer.

Raises:

• ValueError: If the graph def would be too large.

```
tf.Graph.finalize()
```

Finalizes this graph, making it read-only.

After calling g.finalize(), no new operations can be added to g.

This method is used to ensure that no operations are added to a graph when it is shared between multiple threads, for example when using aQueueRunner.

```
tf.Graph.finalized
```

True if this graph has been finalized.

```
tf.Graph.control_dependencies(control_inputs)
```

Returns a context manager that specifies control dependencies.

Use with the with keyword to specify that all operations constructed within the context should have control dependencies

on control inputs. For example:

```
with g.control_dependencies([a, b, c]):
    # `d` and `e` will only run after `a`, `b`, and `c` have
executed.
    d = ...
    e = ...
```

Multiple calls to control_dependencies() can be nested, and in that case a new operation will have control dependencies on the union of control inputs from all active contexts.

```
with g.control_dependencies([a, b]):
    # Ops constructed here run after `a` and `b`.
    with g.control_dependencies([c, d]):
     # Ops constructed here run after `a`, `b`, `c`, and `d`.
```

You can pass None to clear the control dependencies:

```
with g.control_dependencies([a, b]):
    # Ops constructed here run after `a` and `b`.
    with g.control_dependencies(None):
        # Ops constructed here run normally, not waiting for either
        `a` or `b`.
        with g.control_dependencies([c, d]):
            # Ops constructed here run after `c` and `d`, also not
        waiting
            # for either `a` or `b`.
```

N.B. The control dependencies context applies only to ops that are constructed within the context. Merely using an op or tensor in the context does not add a control dependency. The following example illustrates this point:

```
# WRONG
def my_func(pred, tensor):
    t = tf.matmul(tensor, tensor)
    with tf.control_dependencies([pred]):
        # The matmul op is created outside the context, so no control
        # dependency will be added.
        return t

# RIGHT
def my_func(pred, tensor):
    with tf.control_dependencies([pred]):
        # The matmul op is created in the context, so a control
dependency
        # will be added.
        return tf.matmul(tensor, tensor)
```

Args:

• control_inputs: A list of Operation or Tensor objects which must be executed or computed before running the operations defined in the context. Can also be None to clear the control dependencies.

Returns:

A context manager that specifies control dependencies for all operations constructed within the context.

Raises:

TypeError: If control_inputs is not a list

of Operation or Tensor objects.

```
tf.Graph.device(device name or function)
```

Returns a context manager that specifies the default device to use.

The device_name_or_function argument may either be a device name string, a device function, or None:

- If it is a device name string, all operations constructed in this context will be assigned to the device with that name, unless overridden by a nested device() context.
- If it is a function, it will be treated as function from Operation objects to device name strings, and invoked each time a new Operation is created. The Operation will be assigned to the device with the returned name.
- If it is None, all device() invocations from the enclosing context will be ignored.

For example:

```
with g.device('/gpu:0'):
    # All operations constructed in this context will be placed
    # on GPU 0.
    with g.device(None):
        # All operations constructed in this context will have no
        # assigned device.

# Defines a function from `Operation` to device string.
def matmul_on_gpu(n):
    if n.type == "MatMul":
        return "/gpu:0"
    else:
```

```
return "/cpu:0"
with g.device(matmul_on_gpu):
    # All operations of type "MatMul" constructed in this context
    # will be placed on GPU 0; all other operations will be placed
    # on CPU 0.
```

Args:

 device_name_or_function: The device name or function to use in the context.

Returns:

A context manager that specifies the default device to use for newly created ops.

```
tf.Graph.name scope(name)
```

Returns a context manager that creates hierarchical names for operations.

A graph maintains a stack of name scopes. A with

name_scope (...): statement pushes a new name onto the stack for the lifetime of the context.

The name argument will be interpreted as follows:

A string (not ending with '/') will create a new name scope, in
which name is appended to the prefix of all operations created in the
context. If name has been used before, it will be made unique by
callingself.unique name (name).

- A scope previously captured from a with g.name_scope(...) as
 scope: statement will be treated as an "absolute" name scope, which makes it possible to re-enter existing scopes.
- A value of None or the empty string will reset the current name scope to the top-level (empty) name scope.

For example:

```
with tf.Graph().as default() as g:
 c = tf.constant(5.0, name="c")
 assert c.op.name == "c"
 c 1 = tf.constant(6.0, name="c")
 assert c 1.op.name == "c 1"
 # Creates a scope called "nested"
 with g.name scope("nested") as scope:
   nested c = tf.constant(10.0, name="c")
   assert nested c.op.name == "nested/c"
   # Creates a nested scope called "inner".
   with g.name scope("inner"):
     nested inner c = tf.constant(20.0, name="c")
     assert nested inner c.op.name == "nested/inner/c"
   # Create a nested scope called "inner_1".
   with g.name scope("inner"):
     nested inner 1 c = tf.constant(30.0, name="c")
     assert nested inner 1 c.op.name == "nested/inner 1/c"
     # Treats `scope` as an absolute name scope, and
     # switches to the "nested/" scope.
     with g.name scope(scope):
      nested d = tf.constant(40.0, name="d")
      assert nested d.op.name == "nested/d"
      with g.name_scope(""):
        e = tf.constant(50.0, name="e")
        assert e.op.name == "e"
```

The name of the scope itself can be captured by with

```
g.name_scope(...) as scope:, which stores the name of the scope
```

in the variable scope. This value can be used to name an operation that represents the overall result of executing the ops in a scope. For example:

```
inputs = tf.constant(...)
with g.name_scope('my_layer') as scope:
  weights = tf.Variable(..., name="weights")
  biases = tf.Variable(..., name="biases")
  affine = tf.matmul(inputs, weights) + biases
  output = tf.nn.relu(affine, name=scope)
```

Args:

name: A name for the scope.

Returns:

A context manager that installs name as a new name scope.

A Graph instance supports an arbitrary number of "collections" that are identified by name. For convenience when building a large graph, collections can store groups of related objects: for example,

the tf. Variable uses a collection

(named tf.GraphKeys.VARIABLES) for all variables that are created during the construction of a graph. The caller may define additional collections by specifying a new name.

```
tf.Graph.add to collection(name, value)
```

Stores value in the collection with the given name.

Note that collections are not sets, so it is possible to add a value to a collection several times.

Args:

- name: The key for the collection. The GraphKeys class contains many standard names for collections.
- value: The value to add to the collection.

```
tf.Graph.get collection(name, scope=None)
```

Returns a list of values in the collection with the given name.

Args:

- name: The key for the collection. For example, the GraphKeys class contains many standard names for collections.
- scope: (Optional.) If supplied, the resulting list is filtered to include only items whose name begins with this string.

Returns:

The list of values in the collection with the given name, or an empty list if no value has been added to that collection. The list contains the values in the order under which they were collected.

```
tf.Graph.as_graph_element(obj, allow_tensor=True,
allow operation=True)
```

Returns the object referred to by obj, as an Operation or Tensor.

This function validates that obj represents an element of this graph, and gives an informative error message if it is not.

This function is the canonical way to get/validate an object of one of the allowed types from an external argument reference in the Session API.

This method may be called concurrently from multiple threads.

Args:

• obj: A Tensor, an Operation, or the name of a tensor or operation.

Can also be any object with an_as_graph_element() method that returns a value of one of these types.

- allow tensor: If true, obj may refer to a Tensor.
- allow operation: If true, obj may refer to an Operation.

Returns:

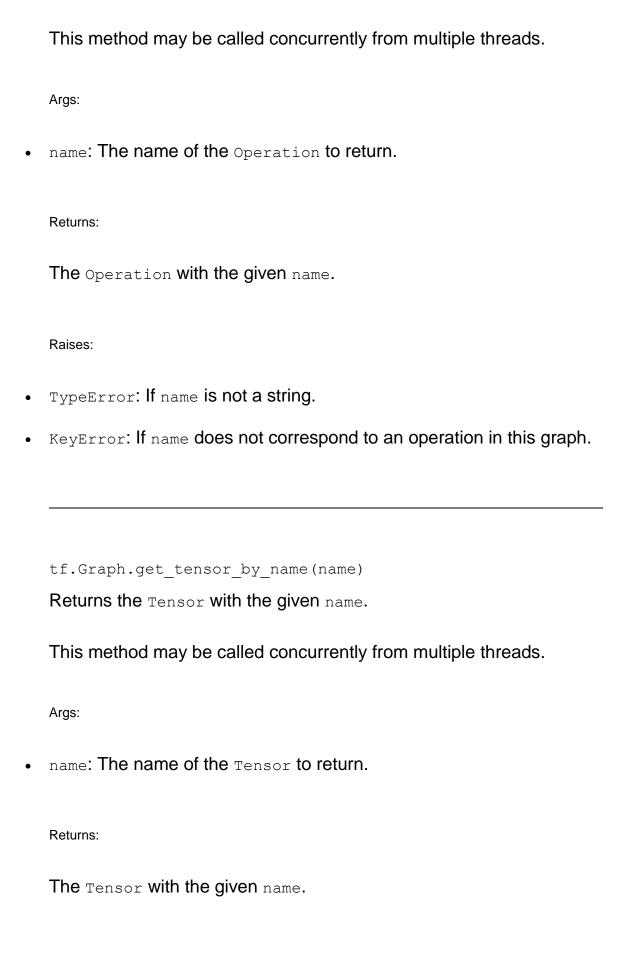

The Tensor or Operation in the Graph corresponding to obj.

Raises:

- TypeError: If obj is not a type we support attempting to convert to types.
- valueError: If obj is of an appropriate type but invalid. For example, an invalid string.
- KeyError: If obj is not an object in the graph.

tf.Graph.get operation by name(name)

Returns the Operation with the given name.

Raises:

- TypeError: If name is not a string.
- KeyError: If name does not correspond to a tensor in this graph.

```
tf.Graph.get operations()
```

Return the list of operations in the graph.

You can modify the operations in place, but modifications to the list such as inserts/delete have no effect on the list of operations known to the graph.

This method may be called concurrently from multiple threads.

Returns:

A list of Operations.

tf.Graph.seed

tf.Graph.unique name(name)

Return a unique operation name for name.

Note: You rarely need to call <code>unique_name()</code> directly. Most of the time you just need to create <code>with g.name_scope()</code> blocks to generate structured names.

unique name is used to generate structured names, separated

by "/", to help identify operations when debugging a graph.

Operation names are displayed in error messages reported by the TensorFlow runtime, and in various visualization tools such as TensorBoard.

Args:

name: The name for an operation.

Returns:

A string to be passed to <code>create_op()</code> that will be used to name the operation being created.

```
tf.Graph.version
```

Returns a version number that increases as ops are added to the graph.

Note that this is unrelated to the **GraphDef version**.

```
tf.Graph.graph def versions
```

The GraphDef version information of this graph.

For details on the meaning of each version, see GraphDef.

Returns:

```
tf.Graph.create_op(op_type, inputs, dtypes,
input_types=None, name=None, attrs=None, op_def=None,
compute_shapes=True, compute_device=True)
```

Creates an Operation in this graph.

This is a low-level interface for creating an <code>Operation</code>. Most programs will not call this method directly, and instead use the Python op constructors, such as <code>tf.constant()</code>, which add ops to the default graph.

Args:

- op_type: The Operation type to create. This corresponds to the OpDef.name field for the proto that defines the operation.
- inputs: A list of Tensor objects that will be inputs to the Operation.
- dtypes: A list of DType objects that will be the types of the tensors that the operation produces.
- input_types: (Optional.) A list of DTypes that will be the types of the tensors that the operation consumes. By default, uses the base DType of each input in inputs. Operations that expect reference-typed inputs must specify input types explicitly.
- name: (Optional.) A string name for the operation. If not specified, a
 name is generated based on op type.

- attrs: (Optional.) A dictionary where the key is the attribute name (a string) and the value is the respective attr attribute of the NodeDef proto that will represent the operation (an AttrValue proto).
- op_def: (Optional.) The opDef proto that describes the op_type that the operation will have.
- compute_shapes: (Optional.) If True, shape inference will be performed to compute the shapes of the outputs.
- compute_device: (Optional.) If True, device functions will be executed to compute the device property of the Operation.

Raises:

• TypeError: if any of the inputs is not a Tensor.

Returns:

An Operation object.

```
tf.Graph.gradient override map(op type map)
```

EXPERIMENTAL: A context manager for overriding gradient functions.

This context manager can be used to override the gradient function that will be used for ops within the scope of the context.

For example:

@tf.RegisterGradient("CustomSquare")

Args:

 op_type_map: A dictionary mapping op type strings to alternative op type strings.

Returns:

A context manager that sets the alternative op type to be used for one or more ops created in that context.

Raises:

 TypeError: If op_type_map is not a dictionary mapping strings to strings.

Other Methods

```
tf.Graph.add to collections (names, value)
```

Stores value in the collections given by names.

Note that collections are not sets, so it is possible to add a value to a collection several times. This function makes sure that duplicates

in names are ignored, but it will not check for pre-existing membership of value in any of the collections in names.

Args:

- names: The keys for the collections to add to. The GraphKeys class contains many standard names for collections.
- value: The value to add to the collections.

```
tf.Graph.get all collection keys()
```

Returns a list of collections used in this graph.

```
class tf.Operation
```

Represents a graph node that performs computation on tensors.

An Operation is a node in a TensorFlow Graph that takes zero or more Tensor objects as input, and produces zero or more Tensor objects as output. Objects of type Operation are created by calling a Python op constructor (such as tf.matmul()) or Graph.create op().

For example c = tf.matmul(a, b) creates an Operation of type "MatMul" that takes tensors a and b as input, and produces c as output.

After the graph has been launched in a session, an <code>operation</code> can be executed by passing it to <code>session.run().op.run()</code> is a shortcut for calling <code>tf.get_default_session().run(op)</code>.

tf.Operation.name

The full name of this operation.

tf.Operation.type

The type of the op (e.g. "MatMul").

tf.Operation.inputs

The list of Tensor objects representing the data inputs of this op.

tf.Operation.control inputs

The Operation objects on which this op has a control dependency. Before this op is executed, TensorFlow will ensure that the operations in <code>self.control_inputs</code> have finished executing. This mechanism can be used to run ops sequentially for performance reasons, or to ensure that the side effects of an op are observed in the correct order.

Returns: A list of Operation objects. tf.Operation.outputs The list of Tensor objects representing the outputs of this op. tf.Operation.device The name of the device to which this op has been assigned, if any. Returns: The string name of the device to which this op has been assigned, or an empty string if it has not been assigned to a device.

tf.Operation.graph

The Graph that contains this operation.

tf.Operation.run(feed_dict=None, session=None)

Runs this operation in a Session.

Calling this method will execute all preceding operations that produce the inputs needed for this operation.

N.B. Before invoking Operation.run(), its graph must have been
launched in a session, and either a default session must be available,
or session must be specified explicitly.
Args:
feed_dict: A dictionary that maps Tensor objects to feed values.
See Session.run() for a description of the valid feed values.
session: (Optional.) The Session to be used to run to this operation.
If none, the default session will be used.
tf.Operation.get_attr(name)
Returns the value of the attr of this op with the given name.
Args:
name: The name of the attr to fetch.
name. The name of the attributeton.
Returns:
The value of the attr, as a Python object.
Raises:
ValueError: If this op does not have an attr with the given name.

•

```
tf.Operation.traceback
```

Returns the call stack from when this operation was constructed.

Other Methods

```
tf.Operation.__init__(node_def, g, inputs=None,
output_types=None, control_inputs=None, input_types=None,
original_op=None, op_def=None)
```

Creates an Operation.

NOTE: This constructor validates the name of the <code>operation</code> (passed as <code>node_def.name</code>). Valid <code>operation</code>names match the following regular expression:

```
[A-Za-z0-9.][A-Za-z0-9...]
```

Args:

- node_def: graph_pb2.NodeDef. NodeDef for the Operation. Used for attributes ofgraph_pb2.NodeDef, typically name, op, and device.
 The input attribute is irrelevant here as it will be computed when generating the model.
- g: Graph. The parent graph.
- inputs: list of Tensor objects. The inputs to this Operation.
- output_types: list of DType objects. List of the types of the Tensors computed by this operation. The length of this list indicates the number of output endpoints of the Operation.
- control_inputs: list of operations or tensors from which to have a control dependency.

- input_types: List of DType objects representing the types of the tensors accepted by the Operation. By default
 uses [x.dtype.base_dtype for x in inputs]. Operations that expect reference-typed inputs must specify these explicitly.
- original_op: Optional. Used to associate the new Operation with an existing Operation (for example, a replica with the op that was replicated).
- op_def: Optional. The op_def_pb2.OpDef proto that describes the op type that this Operationrepresents.

Raises:

- TypeError: if control inputs are not Operations or Tensors, or
 if node_def is not a NodeDef, or if g is not aGraph, or if inputs are
 not tensors, or if inputs and input_types are incompatible.
- ValueError: if the node_def name is not valid.

tf.Operation.node def

Returns a serialized NodeDef representation of this operation.

Returns:

A NodeDef protocol buffer.

```
tf.Operation.op def
```

Returns the Opdef proto that represents the type of this op.

Returns:

An OpDef protocol buffer.

tf.Operation.values()

DEPRECATED: Use outputs.

class tf.Tensor

Represents a value produced by an Operation.

A Tensor is a symbolic handle to one of the outputs of an Operation. It does not hold the values of that operation's output, but instead provides a means of computing those values in a

TensorFlow Session.

This class has two primary purposes:

- A Tensor can be passed as an input to another Operation. This
 builds a dataflow connection between operations, which enables
 TensorFlow to execute an entire Graph that represents a large, multistep computation.
- 2. After the graph has been launched in a session, the value of the Tensor can be computed by passing it

```
toSession.run().t.eval() is a shortcut for
```

```
calling tf.get default session().run(t).
```

In the following example, c, d, and e are symbolic Tensor objects,

whereas result is a numpy array that stores a concrete value:

```
# Build a dataflow graph.
c = tf.constant([[1.0, 2.0], [3.0, 4.0]])
d = tf.constant([[1.0, 1.0], [0.0, 1.0]])
e = tf.matmul(c, d)

# Construct a `Session` to execute the graph.
sess = tf.Session()

# Execute the graph and store the value that `e` represents in `result`.
result = sess.run(e)
```

tf.Tensor.dtype

The DType of elements in this tensor.

tf.Tensor.name

The string name of this tensor.

tf.Tensor.value index

The index of this tensor in the outputs of its Operation.

tf.Tensor.graph

The Graph that contains this tensor.

tf.Tensor.op

The Operation that produces this tensor as an output.

tf.Tensor.consumers()

Returns a list of Operations that consume this tensor.

Returns:

A list of OperationS.

tf.Tensor.eval(feed dict=None, session=None)

Evaluates this tensor in a Session.

Calling this method will execute all preceding operations that produce the inputs needed for the operation that produces this tensor.

N.B. Before invoking Tensor.eval(), its graph must have been launched in a session, and either a default session must be available, or session must be specified explicitly.

Args:

- feed_dict: A dictionary that maps Tensor objects to feed values.
 See Session.run() for a description of the valid feed values.
- session: (Optional.) The session to be used to evaluate this tensor.
 If none, the default session will be used.

Returns:

A numpy array corresponding to the value of this tensor.

```
tf.Tensor.get shape()
```

Returns the TensorShape that represents the shape of this tensor. The shape is computed using shape inference functions that are registered for each Operation type usingtf.RegisterShape.

See TensorShape for more details of what a shape represents.

The inferred shape of a tensor is used to provide shape information without having to launch the graph in a session. This can be used for debugging, and providing early error messages. For example:

```
c = tf.constant([[1.0, 2.0, 3.0], [4.0, 5.0, 6.0]])

print(c.get_shape())
==> TensorShape([Dimension(2), Dimension(3)])

d = tf.constant([[1.0, 0.0], [0.0, 1.0], [1.0, 0.0], [0.0, 1.0]])

print(d.get_shape())
==> TensorShape([Dimension(4), Dimension(2)])

# Raises a ValueError, because `c` and `d` do not have compatible # inner dimensions.
e = tf.matmul(c, d)
```

```
f = tf.matmul(c, d, transpose_a=True, transpose_b=True)
print(f.get_shape())
==> TensorShape([Dimension(3), Dimension(4)])
```

In some cases, the inferred shape may have unknown dimensions. If the caller has additional information about the values of these dimensions, Tensor.set_shape() can be used to augment the inferred shape.

Returns:

A TensorShape representing the shape of this tensor.

```
tf.Tensor.set shape(shape)
```

Updates the shape of this tensor.

This method can be called multiple times, and will merge the given shape with the current shape of this tensor. It can be used to provide additional information about the shape of this tensor that cannot be inferred from the graph alone. For example, this can be used to provide additional information about the shapes of images:

Args:

• shape: A TensorShape representing the shape of this tensor.

Raises:

• ValueError: If shape is not compatible with the current shape of this tensor.

Other Methods

tf.Tensor.__init__(op, value_index, dtype)

Creates a new Tensor.

Args:

- op: An Operation. Operation that computes this tensor.
- value_index: An int. Index of the operation's endpoint that produces this tensor.
- dtype: A DType. Type of elements stored in this tensor.

Raises:

• TypeError: If the op is not an Operation.

The name of the device on which this tensor will be produced, or None.

Tensor types

```
class tf.DType
```

Represents the type of the elements in a Tensor.

The following DType objects are defined:

- tf.float32: 32-bit single-precision floating-point.
- tf.float64: 64-bit double-precision floating-point.
- tf.bfloat16: 16-bit truncated floating-point.
- tf.complex64: 64-bit single-precision complex.
- tf.int8: 8-bit signed integer.
- tf.uint8: 8-bit unsigned integer.
- tf.uint16: 16-bit unsigned integer.
- tf.int16: 16-bit signed integer.
- tf.int32: 32-bit signed integer.
- tf.int64: 64-bit signed integer.
- tf.bool: Boolean.
- tf.string: String.
- tf.qint8: Quantized 8-bit signed integer.
- tf.quint8: Quantized 8-bit unsigned integer.

- tf.qint16: Quantized 16-bit signed integer.
- tf.quint16: Quantized 16-bit unsigned integer.
- tf.qint32: Quantized 32-bit signed integer.

In addition, variants of these types with the _ref suffix are defined for reference-typed tensors.

The tf.as_dtype() function converts numpy types and string type names to a DType object.

```
tf.DType.is compatible with (other)
```

Returns True if the other DType will be converted to this DType.

The conversion rules are as follows:

```
DType(T) .is_compatible_with(DType(T)) == True
DType(T) .is_compatible_with(DType(T).as_ref) == True
DType(T).as_ref.is_compatible_with(DType(T)) == False
DType(T).as_ref.is_compatible_with(DType(T).as_ref) == True
```

Args:

other: A DType (or object that may be converted to a DType).

Returns:

True if a Tensor of the other DType will be implicitly converted to this DType.

tf.DType.name

Returns the string name for this DType.

tf.DType.base_dtype

Returns a non-reference DType based on this DType.

tf.DType.is_ref_dtype

Returns True if this DType represents a reference type.

tf.DType.as ref

Returns a reference DType based on this DType.

tf.DType.is_floating

Returns whether this is a (real) floating point type.

tf.DType.is integer

Returns whether this is a (non-quantized) integer type.

tf.DType.is quantized

Returns whether this is a quantized data type.

tf.DType.is_unsigned

Returns whether this type is unsigned.

Non-numeric, unordered, and quantized types are not considered unsigned, and this function returns False.

Returns:

Whether a DType is unsigned.

tf.DType.as numpy dtype

Returns a numpy.dtype based on this DType.

tf.DType.as_datatype_enum

Returns a types pb2.DataType enum value based on this DType.

Other Methods

```
tf.DType.__init__(type_enum)
```

Creates a new DataType.

NOTE(mrry): In normal circumstances, you should not need to construct a DataType object directly. Instead, use

```
the tf.as dtype() function.
```

Args:

• type enum: A types pb2.DataType enum value.

Raises:

• TypeError: If type enum is not a value types pb2.DataType.

```
tf.DType.max
```

Returns the maximum representable value in this data type.

Raises:

• TypeError: if this is a non-numeric, unordered, or quantized type.

```
tf.DType.min
```

Returns the minimum representable value in this data type.

	Raises:
•	TypeError: if this is a non-numeric, unordered, or quantized type.
	tf.as_dtype(type_value)
	Converts the given type_value to a DType.
	Args:
•	type_value: A value that can be converted to a tf.DType object.
	This may currently be a tf.DTypeobject, a DataType enum, a string
	type name, or a numpy.dtype.
	Returns:
	A DType corresponding to type_value.
	Raises:
•	TypeError: If type_value cannot be converted to a DType.
	Utility functions
	tf.device(dev)

Wrapper for Graph.device() using the default graph. See Graph.device() for more details. Args: device_name_or_function: The device name or function to use in the context. Returns: A context manager that specifies the default device to use for newly created ops. tf.name scope(name) Wrapper for Graph.name scope() using the default graph. See Graph.name scope() for more details. Args: name: A name for the scope. Returns: A context manager that installs name as a new name scope in the default graph.

```
tf.control dependencies(control inputs)
```

Wrapper for Graph.control_dependencies() using the default graph.

See Graph.control dependencies () for more details.

Args:

• control_inputs: A list of Operation or Tensor objects which must be executed or computed before running the operations defined in the context. Can also be None to clear the control dependencies.

Returns:

A context manager that specifies control dependencies for all operations constructed within the context.

```
tf.convert_to_tensor(value, dtype=None, name=None,
as ref=False)
```

Converts the given value to a Tensor.

This function converts Python objects of various types to Tensor objects. It accepts Tensor objects, numpy arrays, Python lists, and Python scalars. For example:

```
import numpy as np
array = np.random.rand(32, 100, 100)

def my_func(arg):
    arg = tf.convert_to_tensor(arg, dtype=tf.float32)
    return tf.matmul(arg, arg) + arg

# The following calls are equivalent.
value_1 = my_func(tf.constant([[1.0, 2.0], [3.0, 4.0]]))
value_2 = my_func([[1.0, 2.0], [3.0, 4.0]])
```

```
value_3 = my_func(np.array([[1.0, 2.0], [3.0, 4.0]],
dtype=np.float32))
```

This function can be useful when composing a new operation in Python (such as my_func in the example above). All standard Python op constructors apply this function to each of their Tensor-valued inputs, which allows those ops to accept numpy arrays, Python lists, and scalars in addition to Tensor objects.

Args:

- value: An object whose type has a registered Tensor conversion function.
- dtype: Optional element type for the returned tensor. If missing, the
 type is inferred from the type of value.
- name: Optional name to use if a new Tensor is created.
- as_ref: True if we want the result as a ref tensor.

Returns:

A Tensor based on value.

Raises:

- TypeError: If no conversion function is registered for value.
- RuntimeError: If a registered conversion function returns an invalid value.

```
tf.convert_to_tensor_or_indexed_slices(value, dtype=None,
name=None, as ref=False)
```

Converts the given object to a Tensor or an IndexedSlices.

If value is an IndexedSlices it is returned unmodified. Otherwise, it is converted to a Tensor usingconvert_to_tensor().

Args:

- value: An IndexedSlices or an object that can be consumed
 by convert to tensor().
- dtype: (Optional.) The required DType of the
 returned Tensor or IndexedSlices.
- name: (Optional.) A name to use if a new Tensor is created.
- as_ref: True if the caller wants the results as ref tensors.

Returns:

An Tensor or an IndexedSlices based on value.

Raises:

• ValueError: If dtype does not match the element type of value.

```
tf.get default graph()
```

Returns the default graph for the current thread.

The returned graph will be the innermost graph on which

a Graph.as_default() context has been entered, or a global default graph if none has been explicitly created.

NOTE: The default graph is a property of the current thread. If you create a new thread, and wish to use the default graph in that thread,

you must explicitly add a with g.as_default(): in that thread's function.

Returns:

The default Graph being used in the current thread.

```
tf.reset_default_graph()
```

Clears the default graph stack and resets the global default graph.

NOTE: The default graph is a property of the current thread. This function applies only to the current thread. Calling this function while

a $\tt tf.Session$ or $\tt tf.InteractiveSession$ is active will result in undefined behavior. Using any previously

created tf.Operation or tf.Tensor objects after calling this function will result in undefined behavior.

```
tf.import_graph_def(graph_def, input_map=None,
return elements=None, name=None, op dict=None)
```

Imports the TensorFlow graph in graph def into the Python Graph.

This function provides a way to import a serialized

TensorFlow GraphDef protocol buffer, and extract individual objects

in the GraphDef as Tensor and Operation objects.

See Graph.as graph def() for a way to create a GraphDef proto.

Args:

- graph_def: A GraphDef proto containing operations to be imported into the default graph.
- input_map: A dictionary mapping input names (as strings)
 in graph_def to Tensor objects. The values of the named input tensors in the imported graph will be re-mapped to the respective Tensor values.
- return_elements: A list of strings containing operation names
 in graph_def that will be returned asoperation objects; and/or
 tensor names in graph_def that will be returned as Tensor objects.
- name: (Optional.) A prefix that will be prepended to the names
 in graph def. Defaults to "import".
- op_dict: (Optional.) A dictionary mapping op type names
 to OpDef protos. Must contain an OpDef proto for each op type named
 in graph_def. If omitted, uses the OpDef protos registered in the global registry.

Returns:

A list of Operation and/or Tensor objects from the imported graph, corresponding to the names inreturn_elements.

Raises:

- TypeError: If graph_def is not a GraphDef proto, input_map is not a
 dictionary mapping strings to Tensor objects, or return_elements is
 not a list of strings.
- ValueError: If input_map, or return_elements contains names that
 do not appear in graph_def, orgraph_def is not well-formed (e.g. it
 refers to an unknown tensor).

```
tf.load op library(library filename)
```

Loads a TensorFlow plugin, containing custom ops and kernels.

Pass "library_filename" to a platform-specific mechanism for dynamically loading a library. The rules for determining the exact location of the library are platform-specific and are not documented here. Expects the symbols "RegisterOps", "RegisterKernels", and "GetOpList", to be defined in the library.

Args:

 library_filename: Path to the plugin. Relative or absolute filesystem path to a dynamic library file.

Returns:

A python module containing the Python wrappers for Ops defined in the plugin.

Raises:

 RuntimeError: when unable to load the library or get the python wrappers.

Graph collections

```
tf.add_to_collection(name, value)
Wrapper for Graph.add_to_collection() using the default graph.
See Graph.add_to_collection() for more details.
Args:
```

• name: The key for the collection. For example, the GraphKeys class contains many standard names for collections.

value: The value to add to the collection.

```
tf.get_collection(key, scope=None)
```

Wrapper for Graph.get collection() using the default graph.

See Graph.get_collection() for more details.

Args:

• key: The key for the collection. For example, the GraphKeys class contains many standard names for collections.

 scope: (Optional.) If supplied, the resulting list is filtered to include only items whose name begins with this string.

Returns:

The list of values in the collection with the given name, or an empty list if no value has been added to that collection. The list contains the values in the order under which they were collected.

```
class tf.GraphKeys
```

Standard names to use for graph collections.

The standard library uses various well-known names to collect and retrieve values associated with a graph. For example, the tf.Optimizer subclasses default to optimizing the variables collected undertf.GraphKeys.TRAINABLE_VARIABLES if none is specified, but it is also possible to pass an explicit list of variables. The following standard keys are defined:

- VARIABLES: the Variable objects that comprise a model, and must be saved and restored together. Seetf.all_variables() for more details.
- TRAINABLE_VARIABLES: the subset of Variable objects that will be trained by an optimizer. Seetf.trainable_variables() for more details.
- SUMMARIES: the summary Tensor objects that have been created in the graph. Seetf.merge_all_summaries() for more details.

- QUEUE_RUNNERS: the QueueRunner objects that are used to produce input for a computation. Seetf.start_queue_runners() for more details.
- MOVING_AVERAGE_VARIABLES: the subset of Variable objects that will also keep moving averages.

Seetf.moving average variables() for more details.

- REGULARIZATION_LOSSES: regularization losses collected during graph construction.
- WEIGHTS: weights inside neural network layers
- BIASES: biases inside neural network layers
- ACTIVATIONS: activations of neural network layers

Defining new operations

class tf.RegisterGradient

A decorator for registering the gradient function for an op type.

This decorator is only used when defining a new op type. For an op with m inputs and n outputs, the gradient function is a function that takes the original Operation and n Tensor objects (representing the gradients with respect to each output of the op), and returns m Tensor objects (representing the partial gradients with respect to each input of the op).

For example, assuming that operations of type "sub" take two inputs x and y, and return a single output x - y, the following gradient function would be registered:

```
@tf.RegisterGradient("Sub")
def _sub_grad(unused_op, grad):
  return grad, tf.neg(grad)
```

The decorator argument op type is the string type of an operation.

This corresponds to the OpDef.name field for the proto that defines the operation.

```
tf.RegisterGradient. init (op type)
```

Creates a new decorator with op type as the Operation type.

Args:

op_type: The string type of an operation. This corresponds to
 the OpDef.name field for the proto that defines the operation.

```
tf.NoGradient(op type)
```

Specifies that ops of type op_type do not have a defined gradient. This function is only used when defining a new op type. It may be used for ops such as tf.size() that are not differentiable. For example:

```
tf.NoGradient("Size")
```

Args:

op_type: The string type of an operation. This corresponds to
 the OpDef.name field for the proto that defines the operation.

Raises:

TypeError: If op type is not a string.

```
class tf.RegisterShape
```

A decorator for registering the shape function for an op type.

This decorator is only used when defining a new op type. A shape function is a function from an Operationobject to a list

of TensorShape objects, with one TensorShape for each output of the operation.

For example, assuming that operations of type "Sub" take two

inputs x and y, and return a single output x - y, all with the same shape, the following shape function would be registered:

```
@tf.RegisterShape("Sub")
def _sub_shape(op):
   return
[op.inputs[0].get_shape().merge_with(op.inputs[1].get_shape())]
```

The decorator argument op_type is the string type of an operation.

This corresponds to the OpDef.name field for the proto that defines the operation.

```
tf.RegisterShape.__init__(op_type)
```

Saves the op type as the Operation type.

class tf.TensorShape

Represents the shape of a Tensor.

A TensorShape represents a possibly-partial shape specification for a Tensor. It may be one of the following:

- Fully-known shape: has a known number of dimensions and a known size for each dimension.
- Partially-known shape: has a known number of dimensions, and an unknown size for one or more dimension.
- Unknown shape: has an unknown number of dimensions, and an unknown size in all dimensions.

If a tensor is produced by an operation of type " $F\circ\circ$ ", its shape may be inferred if there is a registered shape function for " $F\circ\circ$ ".

See tf.RegisterShape() for details of shape functions and how to register them. Alternatively, the shape may be set explicitly using Tensor.set shape().

tf.TensorShape.merge with(other)

Returns a TensorShape combining the information

in self and other.

The dimensions in self and other are merged elementwise, according to the rules defined forDimension.merge with().

	Args:
•	other: Another TensorShape.
	Returns:
	A TensorShape containing the combined information
	of self and other.
	Raises:
•	ValueError: If self and other are not compatible.
	tf.TensorShape.concatenate(other)
	Returns the concatenation of the dimension in self and other.
	N.B. If either self or other is completely unknown, concatenation
	will discard information about the other shape. In future, we might support concatenation that preserves this information for use with slicing.
	Args:
•	other: Another TensorShape.
	Returns:
	A TensorShape whose dimensions are the concatenation of the
	dimensions in self and other.

tf.TensorShape.ndims

Returns the rank of this shape, or None if it is unspecified.

tf.TensorShape.dims

Returns a list of Dimensions, or None if the shape is unspecified.

tf.TensorShape.as list()

Returns a list of integers or None for each dimension.

Returns:

A list of integers or None for each dimension.

tf.TensorShape.as_proto()

Returns this shape as a TensorShapeProto.

tf.TensorShape.is_compatible_with(other)

Returns True iff self is compatible with other.

Two possibly-partially-defined shapes are compatible if there exists a fully-defined shape that both shapes can represent. Thus, compatibility allows the shape inference code to reason about partially-defined shapes. For example:

- TensorShape(None) is compatible with all shapes.
- TensorShape([None, None]) is compatible with all two-dimensional shapes, such as TensorShape([32, 784]), and also TensorShape(None). It is not compatible with, for example, TensorShape([None]) or TensorShape([None, None, None]).
- TensorShape([32, None]) is compatible with all two-dimensional shapes with size 32 in the 0th dimension, and also TensorShape([None, None]) and TensorShape(None). It is not compatible with, for example, TensorShape([32]), TensorShape([32, None, 1]) or TensorShape([64, None]).
- TensorShape([32, 784]) is compatible with itself, and also TensorShape([32, None]), TensorShape([None, 784]), TensorShape([None, None]) and TensorShape(None). It is not compatible with, for example, TensorShape([32, 1, 784]) or TensorShape([None]).

The compatibility relation is reflexive and symmetric, but not transitive. For example, TensorShape([32, 784]) is compatible with

	TensorShape(None), and TensorShape(None) is compatible with TensorShape([4, 4]), but TensorShape([32, 784]) is not compatible with TensorShape([4, 4]).
	Args:
•	other: Another TensorShape.
	Returns:
	True iff self is compatible with other.

```
tf.TensorShape.is fully defined()
```

Returns True iff self is fully defined in every dimension.

```
tf.TensorShape.with rank(rank)
```

Returns a shape based on self with the given rank.

This method promotes a completely unknown shape to one with a known rank.

Args:

• rank: An integer.

Returns:

A shape that is at least as specific as self with the given rank.

Raises:

• ValueError: If self does not represent a shape with the given rank.

```
tf.TensorShape.with_rank_at_least(rank)
```

Returns a shape based on self with at least the given rank.

Args:

rank: An integer.

	Returns:
	A shape that is at least as specific as \mathtt{self} with at least the given rank.
	Raises:
•	ValueError: If self does not represent a shape with at least the
	given rank.
	tf.TensorShape.with_rank_at_most(rank)
	Returns a shape based on self with at most the given rank.
	Args:
•	rank: An integer.
	Returns:
	A shape that is at least as specific as <code>self</code> with at most the given rank.
	Raises:
•	ValueError: If self does not represent a shape with at most the given rank.
	g., c., zam.

```
tf.TensorShape.assert has rank(rank)
  Raises an exception if self is not compatible with the given rank.
  Args:
 rank: An integer.
  Raises:
 ValueError: If self does not represent a shape with the given rank.
  tf.TensorShape.assert same rank(other)
  Raises an exception if self and other do not have compatible ranks.
  Args:
• other: Another TensorShape.
  Raises:
• ValueError: If self and other do not represent shapes with the
  same rank.
  tf.TensorShape.assert is compatible with(other)
  Raises exception if self and other do not represent the same
```

shape.

This method can be used to assert that there exists a shape that both self and other represent.		
Args:		
other: Another TensorShape.		
Raises:		
ValueError: If self and other do not represent the same shape.		
<pre>tf.TensorShape.assert_is_fully_defined() Raises an exception if self is not fully defined in every dimension.</pre>		
Raises:		
ValueError: If self does not have a known value for every dimension.		
Other Methods		
tf.TensorShapeinit(dims)		
Creates a new TensorShape with the given dimensions.		
Args:		

dims: A list of Dimensions, or None if the shape is unspecified. DEPRECATED: A single integer is treated as a singleton list.
tf.TensorShape.num_elements() Returns the total number of elements, or none for incomplete shapes.
class tf.Dimension Represents the value of one dimension in a TensorShape.
tf.Dimensioninit(value) Creates a new Dimension with the given value.
tf.Dimension.assert_is_compatible_with(other) Raises an exception if other is not compatible with this Dimension.
Args:
other: Another Dimension.
Raises:

 ValueError: If self and other are not compatible (see is_compatible_with).

```
tf.Dimension.is compatible with(other)
```

Returns true if other is compatible with this Dimension.

Two known Dimensions are compatible if they have the same value. An unknown Dimension is compatible with all other Dimensions.

Args:

• other: Another Dimension.

Returns:

True if this Dimension and other are compatible.

```
tf.Dimension.merge with(other)
```

Returns a Dimension that combines the information

in self and other.

Dimensions are combined as follows:

```
Dimension(n) .merge_with(Dimension(n)) == Dimension(n)
Dimension(n) .merge_with(Dimension(None)) == Dimension(n)
Dimension(None).merge_with(Dimension(n)) == Dimension(n)
Dimension(None).merge_with(Dimension(None)) == Dimension(None)
Dimension(n) .merge_with(Dimension(m)) raises ValueError for
n != m
```

• other: Another Dimension.

Returns:

A Dimension containing the combined information of self and other.

Raises:

 ValueError: If self and other are not compatible (see is_compatible_with).

```
tf.Dimension.value
```

The value of this dimension, or None if it is unknown.

```
tf.op scope(values, name, default name=None)
```

Returns a context manager for use when defining a Python op.

This context manager validates that the given values are from the same graph, ensures that that graph is the default graph, and pushes a name scope.

For example, to define a new Python op called my_op:

```
def my_op(a, b, c, name=None):
  with tf.op_scope([a, b, c], name, "MyOp") as scope:
    a = tf.convert_to_tensor(a, name="a")
    b = tf.convert_to_tensor(b, name="b")
    c = tf.convert_to_tensor(c, name="c")
```

```
# Define some computation that uses `a`, `b`, and `c`.
return foo_op(..., name=scope)
```

- values: The list of Tensor arguments that are passed to the op function.
- name: The name argument that is passed to the op function.
- default_name: The default name to use if the name argument
 is None.

Returns:

A context manager for use in defining Python ops. Yields the name scope.

Raises:

• ValueError: if neither name nor default name is provided.

```
tf.get seed(op seed)
```

Returns the local seeds an operation should use given an op-specific seed.

Given operation-specific seed, op_seed, this helper function returns two seeds derived from graph-level and op-level seeds. Many random operations internally use the two seeds to allow user to change the seed globally for a graph, or for only specific operations. For details on how the graph-level seed interacts with op seeds,

```
See set random seed.
```

op seed: integer.

Returns:

A tuple of two integers that should be used for the local seed of this operation.

For libraries building on TensorFlow

```
tf.register_tensor_conversion_function(base_type,
conversion func, priority=100)
```

Registers a function for converting objects of base type to Tensor.

The conversion function must have the following signature:

```
def conversion_func(value, dtype=None, name=None, as_ref=False):
    # ...
```

It must return a Tensor with the given dtype if specified. If the conversion function creates a new Tensor, it should use the given name if specified. All exceptions will be propagated to the caller. If as_ref is true, the function must return a Tensor reference, such as a Variable.

NOTE: The conversion functions will execute in order of priority, followed by order of registration. To ensure that a conversion function \mathbb{F} runs before another conversion function \mathbb{G} , ensure that \mathbb{F} is registered with a smaller priority than \mathbb{G} .

- base_type: The base type or tuple of base types for all objects
 that conversion func accepts.
- conversion_func: A function that converts instances
 of base type to Tensor.
- priority: Optional integer that indicates the priority for applying this
 conversion function. Conversion functions with smaller priority values
 run earlier than conversion functions with larger priority values.
 Defaults to 100.

Raises:

TypeError: If the arguments do not have the appropriate type.

Other Functions and Classes

class tf.bytes

str(object=") -> string

Return a nice string representation of the object. If the argument is a string, the return value is the same object.

Constants, Sequences, and Random Values

Note: Functions taking Tensor arguments can also take anything

```
accepted by tf.convert to tensor.
```

- tf.random shuffle(value, seed=None, name=None)
- tf.random crop(value, size, seed=None, name=None)
- tf.set random seed(seed)

Constant Value Tensors

TensorFlow provides several operations that you can use to generate constants.

```
tf.zeros(shape, dtype=tf.float32, name=None)
```

Creates a tensor with all elements set to zero.

This operation returns a tensor of type dtype with shape shape and all elements set to zero.

For example:

```
tf.zeros([3, 4], int32) ==> [[0, 0, 0, 0], [0, 0, 0], [0, 0, 0], [0, 0, 0]]
```

Args:

- shape: Either a list of integers, or a 1-D Tensor of type int32.
- dtype: The type of an element in the resulting Tensor.
- name: A name for the operation (optional).

Returns:

A Tensor with all elements set to zero.

```
tf.zeros like(tensor, dtype=None, name=None)
```

Creates a tensor with all elements set to zero.

Given a single tensor (tensor), this operation returns a tensor of the same type and shape as tensor with all elements set to zero.

Optionally, you can use dtype to specify a new type for the returned tensor.

For example:

```
# 'tensor' is [[1, 2, 3], [4, 5, 6]]
tf.zeros_like(tensor) ==> [[0, 0, 0], [0, 0, 0]]
```

- tensor: A Tensor.
- dtype: A type for the returned Tensor. Must

```
be float32, float64, int8, int16, int32, int64, uint8,
or complex64.
```

name: A name for the operation (optional).

Returns:

A Tensor with all elements set to zero.

```
tf.ones(shape, dtype=tf.float32, name=None)
```

Creates a tensor with all elements set to 1.

This operation returns a tensor of type dtype with shape shape and all elements set to 1.

For example:

```
tf.ones([2, 3], int32) ==> [[1, 1, 1], [1, 1, 1]]
```

- shape: Either a list of integers, or a 1-D Tensor of type int32.
- dtype: The type of an element in the resulting Tensor.
- name: A name for the operation (optional).

Returns:

A Tensor with all elements set to 1.

```
tf.ones like(tensor, dtype=None, name=None)
```

Creates a tensor with all elements set to 1.

Given a single tensor (tensor), this operation returns a tensor of the same type and shape as tensor with all elements set to 1.

Optionally, you can specify a new type (dtype) for the returned tensor.

For example:

```
# 'tensor' is [[1, 2, 3], [4, 5, 6]]
tf.ones_like(tensor) ==> [[1, 1, 1], [1, 1, 1]]
```

Args:

- tensor: A Tensor.
- dtype: A type for the returned Tensor. Must

be float32, float64, int8, int16, int32, int64, uint8,

or complex64.

• name: A name for the operation (optional).

Returns:

A Tensor with all elements set to 1.

```
tf.fill(dims, value, name=None)
```

Creates a tensor filled with a scalar value.

This operation creates a tensor of shape dims and fills it with value.

For example:

Args:

- dims: A Tensor of type int32. 1-D. Represents the shape of the output tensor.
- value: A Tensor. 0-D (scalar). Value to fill the returned tensor.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as value.

```
tf.constant(value, dtype=None, shape=None, name='Const')
```

Creates a constant tensor.

The resulting tensor is populated with values of type <code>dtype</code>, as specified by arguments <code>value</code> and (optionally)shape (see examples below).

The argument value can be a constant value, or a list of values of type dtype. If value is a list, then the length of the list must be less than or equal to the number of elements implied by the shape argument (if specified). In the case where the list length is less than the number of elements specified by shape, the last element in the list will be used to fill the remaining entries. The argument shape is optional. If present, it specifies the dimensions of the resulting tensor. If not present, then the tensor is a scalar (0-D) if value is a scalar, or 1-D otherwise.

If the argument dtype is not specified, then the type is inferred from the type of value.

For example:

- value: A constant value (or list) of output type dtype.
- dtype: The type of the elements of the resulting tensor.
- shape: Optional dimensions of resulting tensor.
- name: Optional name for the tensor.

Returns:

A Constant Tensor.

Sequences

```
tf.linspace(start, stop, num, name=None)
```

Generates values in an interval.

A sequence of num evenly-spaced values are generated beginning at start. If num > 1, the values in the sequence increase by stop - start / num - 1, so that the last one is exactly stop.

For example:

```
tf.linspace(10.0, 12.0, 3, name="linspace") => [ 10.0 11.0 12.0]
```

Args:

- start: A Tensor. Must be one of the followingtypes: float32, float64. First entry in the range.
- stop: A Tensor. Must have the same type as start. Last entry in the range.
- num: A Tensor of type int32. Number of values to generate.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as start. 1-D. The generated values.

```
tf.range(start, limit=None, delta=1, name='range')
```

Creates a sequence of integers.

Creates a sequence of integers that begins at start and extends by increments of delta up to but not including limit.

Like the Python builtin range, start defaults to 0, so that range(n) = range(0, n).

For example:

```
# 'start' is 3
# 'limit' is 18
# 'delta' is 3
tf.range(start, limit, delta) ==> [3, 6, 9, 12, 15]
# 'limit' is 5
tf.range(limit) ==> [0, 1, 2, 3, 4]
```

- start: A 0-D (scalar) of type int32. First entry in sequence. Defaults to 0.
- limit: A 0-D (scalar) of type int32. Upper limit of sequence, exclusive.
- delta: A 0-D Tensor (scalar) of type int32. Optional. Default is 1.
 Number that increments start.
- name: A name for the operation (optional).

Returns:

An 1-D int32 Tensor.

Random Tensors

TensorFlow has several ops that create random tensors with different distributions. The random ops are stateful, and create new random values each time they are evaluated.

The seed keyword argument in these functions acts in conjunction with the graph-level random seed. Changing either the graph-level seed using set_random_seed or the op-level seed will change the underlying seed of these operations. Setting neither graph-level nor op-level seed, results in a random seed for all operations.

Seeset_random_seed for details on the interaction between operation-level and graph-level random seeds.

Examples:

```
# Create a tensor of shape [2, 3] consisting of random normal
values, with mean
# -1 and standard deviation 4.
norm = tf.random_normal([2, 3], mean=-1, stddev=4)

# Shuffle the first dimension of a tensor
c = tf.constant([[1, 2], [3, 4], [5, 6]])
shuff = tf.random_shuffle(c)

# Each time we run these ops, different results are generated
sess = tf.Session()
print(sess.run(norm))
print(sess.run(norm))

# Set an op-level seed to generate repeatable sequences across
sessions.
c = tf.constant([[1, 2], [3, 4], [5, 6]])
sess = tf.Session()
```

```
norm = tf.random_normal(c, seed=1234)
print(sess.run(norm))
print(sess.run(norm))
```

Another common use of random values is the initialization of variables. Also see the Variables How To.

```
# Use random uniform values in [0, 1) as the initializer for a
variable of shape
# [2, 3]. The default type is float32.
var = tf.Variable(tf.random_uniform([2, 3]), name="var")
init = tf.initialize_all_variables()

sess = tf.Session()
sess.run(init)
print(sess.run(var))
```

```
tf.random_normal(shape, mean=0.0, stddev=1.0,
dtype=tf.float32, seed=None, name=None)
```

Outputs random values from a normal distribution.

- shape: A 1-D integer Tensor or Python array. The shape of the output tensor.
- mean: A 0-D Tensor or Python value of type dtype. The mean of the normal distribution.
- stddev: A 0-D Tensor or Python value of type dtype. The standard deviation of the normal distribution.
- dtype: The type of the output.
- seed: A Python integer. Used to create a random seed for the distribution. See set random seed for behavior.
- name: A name for the operation (optional).

A tensor of the specified shape filled with random normal values.

```
tf.truncated_normal(shape, mean=0.0, stddev=1.0,
dtype=tf.float32, seed=None, name=None)
```

Outputs random values from a truncated normal distribution.

The generated values follow a normal distribution with specified mean and standard deviation, except that values whose magnitude is more than 2 standard deviations from the mean are dropped and repicked.

Args:

- shape: A 1-D integer Tensor or Python array. The shape of the output tensor.
- mean: A 0-D Tensor or Python value of type dtype. The mean of the truncated normal distribution.
- stddev: A 0-D Tensor or Python value of type dtype. The standard deviation of the truncated normal distribution.
- dtype: The type of the output.
- seed: A Python integer. Used to create a random seed for the distribution. See set_random_seed for behavior.
- name: A name for the operation (optional).

Returns:

A tensor of the specified shape filled with random truncated normal values.

```
tf.random_uniform(shape, minval=0, maxval=None,
dtype=tf.float32, seed=None, name=None)
```

Outputs random values from a uniform distribution.

The generated values follow a uniform distribution in the range [minval, maxval). The lower bound minvalis included in the range, while the upper bound maxval is excluded.

For floats, the default range is [0, 1). For ints, at least maxval must be specified explicitly.

In the integer case, the random integers are slightly biased

unless maxval - minval is an exact power of two. The bias is small for values of maxval - minval significantly smaller than the range of the output (either2**32 or 2**64).

- shape: A 1-D integer Tensor or Python array. The shape of the output tensor.
- minval: A 0-D Tensor or Python value of type dtype. The lower bound on the range of random values to generate. Defaults to 0.
- maxval: A 0-D Tensor or Python value of type dtype. The upper bound on the range of random values to generate. Defaults to 1 if dtype is floating point.
- dtype: The type of the output: float32, float64, int32, or int64.
- seed: A Python integer. Used to create a random seed for the distribution. See set random seed for behavior.

• name: A name for the operation (optional).

Returns:

A tensor of the specified shape filled with random uniform values.

Raises:

ValueError: If dtype is integral and maxval is not specified.

```
tf.random_shuffle(value, seed=None, name=None)
```

Randomly shuffles a tensor along its first dimension.

The tensor is shuffled along dimension 0, such that each <code>value[j]</code> is mapped to one and only one <code>output[i]</code>. For example, a mapping that might occur for a 3x2 tensor is:

```
[[1, 2], [[5, 6], [3, 4], ==> [1, 2], [5, 6]] [3, 4]]
```

Args:

- value: A Tensor to be shuffled.
- seed: A Python integer. Used to create a random seed for the distribution. See set_random_seed for behavior.
- name: A name for the operation (optional).

Returns:

A tensor of same shape and type as value, shuffled along its first dimension.

```
tf.random crop(value, size, seed=None, name=None)
```

Randomly crops a tensor to a given size.

Slices a shape size portion out of value at a uniformly chosen offset.

Requires value.shape >= size.

If a dimension should not be cropped, pass the full size of that dimension. For example, RGB images can be cropped with size =

```
[crop height, crop width, 3].
```

Args:

- value: Input tensor to crop.
- size: 1-D tensor with size the rank of value.
- seed: Python integer. Used to create a random seed.

See set random seed for behavior.

name: A name for this operation (optional).

Returns:

A cropped tensor of the same rank as value and shape size.

```
tf.set random seed(seed)
```

Sets the graph-level random seed.

Operations that rely on a random seed actually derive it from two seeds: the graph-level and operation-level seeds. This sets the graph-level seed.

Its interactions with operation-level seeds is as follows:

- 1. If neither the graph-level nor the operation seed is set: A random seed is used for this op.
- 2. If the graph-level seed is set, but the operation seed is not: The system deterministically picks an operation seed in conjunction with the graph-level seed so that it gets a unique random sequence.
- 3. If the graph-level seed is not set, but the operation seed is set: A default graph-level seed and the specified operation seed are used to determine the random sequence.
- 4. If both the graph-level and the operation seed are set: Both seeds are used in conjunction to determine the random sequence.

To illustrate the user-visible effects, consider these examples:

To generate different sequences across sessions, set neither graphlevel nor op-level seeds:

```
a = tf.random_uniform([1])
b = tf.random_normal([1])

print("Session 1")
with tf.Session() as sess1:
    print(sess1.run(a)) # generates 'A1'
    print(sess1.run(a)) # generates 'A2'
    print(sess1.run(b)) # generates 'B1'
    print(sess1.run(b)) # generates 'B2'

print("Session 2")
with tf.Session() as sess2:
    print(sess2.run(a)) # generates 'A3'
    print(sess2.run(a)) # generates 'A4'
    print(sess2.run(b)) # generates 'B3'
    print(sess2.run(b)) # generates 'B4'
```

To generate the same repeatable sequence for an op across sessions, set the seed for the op:

```
a = tf.random uniform([1], seed=1)
b = tf.random normal([1])
# Repeatedly running this block with the same graph will generate
the same
# sequence of values for 'a', but different sequences of values
for 'b'.
print("Session 1")
with tf.Session() as sess1:
 print(sess1.run(a)) # generates 'A1'
 print(sess1.run(a)) # generates 'A2'
 print(sess1.run(b)) # generates 'B1'
 print(sess1.run(b)) # generates 'B2'
print("Session 2")
with tf.Session() as sess2:
 print(sess2.run(a)) # generates 'A1'
 print(sess2.run(a)) # generates 'A2'
 print(sess2.run(b)) # generates 'B3'
 print(sess2.run(b)) # generates 'B4'
```

To make the random sequences generated by all ops be repeatable across sessions, set a graph-level seed:

```
tf.set_random_seed(1234)
a = tf.random_uniform([1])
b = tf.random_normal([1])

# Repeatedly running this block with the same graph will generate different
# sequences of 'a' and 'b'.
print("Session 1")
with tf.Session() as sess1:
  print(sess1.run(a)) # generates 'A1'
  print(sess1.run(a)) # generates 'A2'
  print(sess1.run(b)) # generates 'B1'
  print(sess1.run(b)) # generates 'B2'

print("Session 2")
with tf.Session() as sess2:
  print(sess2.run(a)) # generates 'A1'
```

```
print(sess2.run(a)) # generates 'A2'
print(sess2.run(b)) # generates 'B1'
print(sess2.run(b)) # generates 'B2'
```

• seed: integer.

Variables

Note: Functions taking Tensor arguments can also take anything accepted by tf.convert_to_tensor.

Variables

class tf. Variable

See the <u>Variables How To</u> for a high level overview.

A variable maintains state in the graph across calls to run(). You add a variable to the graph by constructing an instance of the class <code>Variable</code>.

The <code>variable()</code> constructor requires an initial value for the variable, which can be a <code>Tensor</code> of any type and shape. The initial value defines the type and shape of the variable. After construction, the

type and shape of the variable are fixed. The value can be changed using one of the assign methods. If you want to change the shape of a variable later you have to use an assign Op withvalidate shape=False.

Just like any Tensor, variables created with Variable() can be used as inputs for other Ops in the graph. Additionally, all the operators overloaded for the Tensor class are carried over to variables, so you can also add nodes to the graph by just doing arithmetic on variables.

```
import tensorflow as tf

# Create a variable.
w = tf.Variable(<initial-value>, name=<optional-name>)

# Use the variable in the graph like any Tensor.
y = tf.matmul(w, ...another variable or tensor...)

# The overloaded operators are available too.
z = tf.sigmoid(w + b)

# Assign a new value to the variable with `assign()` or a related method.
w.assign(w + 1.0)
w.assign_add(1.0)
```

When you launch the graph, variables have to be explicitly initialized before you can run Ops that use their value. You can initialize a variable by running its initializer op, restoring the variable from a save file, or simply running anassign Op that assigns a value to the

variable. In fact, the variable initializer op is just an assign Op that assigns the variable's initial value to the variable itself.

```
# Launch the graph in a session.
with tf.Session() as sess:
    # Run the variable initializer.
    sess.run(w.initializer)
    # ...you now can run ops that use the value of 'w'...
```

The most common initialization pattern is to use the convenience function <code>initialize_all_variables()</code> to add an Op to the graph that initializes all the variables. You then run that Op after launching the graph.

```
# Add an Op to initialize all variables.
init_op = tf.initialize_all_variables()

# Launch the graph in a session.
with tf.Session() as sess:
    # Run the Op that initializes all variables.
    sess.run(init_op)
    # ...you can now run any Op that uses variable values...
```

If you need to create a variable with an initial value dependent on another variable, use the other variable'sinitialized_value(). This ensures that variables are initialized in the right order. All variables are automatically collected in the graph where they are created. By default, the constructor adds the new variable to the graph collection <code>GraphKeys.Variables</code>. The convenience

function all variables() returns the contents of that collection.

When building a machine learning model it is often convenient to distinguish betwen variables holding the trainable model parameters and other variables such as a global step variable used to count training steps. To make this easier, the variable constructor supports a trainable=

>bool> parameter. If True, the new variable is also added to the graph collection GraphKeys.TRAINABLE VARIABLES.

The convenience function trainable_variables() returns the contents of this collection. The various Optimizer classes use this collection as the default list of variables to optimize.

Creating a variable.

```
tf.Variable.__init__(initial_value=None, trainable=True,
collections=None, validate_shape=True, name=None,
variable def=None)
```

Creates a new variable with value initial_value.

The new variable is added to the graph collections listed in collections, which defaults to [GraphKeys.VARIABLES]. If trainable is True the variable is also added to the graph collectionGraphKeys.TRAINABLE_VARIABLES.

This constructor creates both a variable Op and an assign Op to set the variable to its initial value.

- initial_value: A Tensor, or Python object convertible to a Tensor.
 The initial value for the Variable. Must have a shape specified
 unless validate shape is set to False.
- trainable: If True, the default, also adds the variable to the graph collection Graph Keys. TRAINABLE_VARIABLES. This collection is used as the default list of variables to use by the Optimizer classes.
- collections: List of graph collections keys. The new variable is added to these collections. Defaults to [GraphKeys.VARIABLES].
- validate_shape: If False, allows the variable to be initialized with a value of unknown shape. If True, the default, the shape
 of initial value must be known.
- name: Optional name for the variable. Defaults to 'Variable' and gets uniquified automatically.
- variable_def: VariableDef protocol buffer. If not None, recreates
 the Variable object with its contents.variable_def and the other
 arguments are mutually exclusive.

Returns:

A Variable.

Raises:

- ValueError: If both variable def and initial_value are specified.
- ValueError: If the initial value is not specified, or does not have a shape and validate shape is True.

```
tf. Variable.initialized value()
```

Returns the value of the initialized variable.

You should use this instead of the variable itself to initialize another variable with a value that depends on the value of this variable.

```
# Initialize 'v' with a random tensor.
v = tf.Variable(tf.truncated_normal([10, 40]))
# Use `initialized_value` to guarantee that `v` has been
# initialized before its value is used to initialize `w`.
# The random values are picked only once.
w = tf.Variable(v.initialized_value() * 2.0)
```

Returns:

A Tensor holding the value of this variable after its initializer has run.

Changing a variable value.

Assigns a new value to the variable.

This is essentially a shortcut for assign (self, value).

Args:

- value: A Tensor. The new value for this variable.
- use locking: If True, use locking during the assignment.

Returns:

A Tensor that will hold the new value of this variable after the assignment has completed.

```
tf.Variable.assign add(delta, use locking=False)
```

Adds a value to this variable.

This is essentially a shortcut for assign add(self, delta).

Args:

- delta: A Tensor. The value to add to this variable.
- use locking: If True, use locking during the operation.

Returns:

A Tensor that will hold the new value of this variable after the addition has completed.

```
tf.Variable.assign sub(delta, use locking=False)
```

Subtracts a value from this variable.

This is essentially a shortcut for assign sub(self, delta).

Args:

- delta: A Tensor. The value to subtract from this variable.
- use locking: If True, use locking during the operation.

Returns:

A Tensor that will hold the new value of this variable after the subtraction has completed.

```
tf.Variable.scatter_sub(sparse_delta, use_locking=False)
Subtracts IndexedSlices from this variable.
```

This is essentially a shortcut for scatter_sub(self,

```
sparse delta.indices, sparse delta.values).
```

- sparse_delta: IndexedSlices to be subtracted from this variable.
- use locking: If True, use locking during the operation.

Returns:

A Tensor that will hold the new value of this variable after the scattered subtraction has completed.

Raises:

• ValueError: if sparse delta is not an IndexedSlices.

```
tf.Variable.count up to(limit)
```

Increments this variable until it reaches limit.

When that Op is run it tries to increment the variable by 1. If incrementing the variable would bring it above limit then the Op raises the exception OutOfRangeError.

If no error is raised, the Op outputs the value of the variable before the increment.

This is essentially a shortcut for count up to (self, limit).

Args:

• limit: value at which incrementing the variable raises an error.

Returns:

A Tensor that will hold the variable value before the increment. If no other Op modifies this variable, the values produced will all be distinct.

```
tf.Variable.eval(session=None)
```

In a session, computes and returns the value of this variable.

This is not a graph construction method, it does not add ops to the graph.

This convenience method requires a session where the graph containing this variable has been launched. If no session is passed, the default session is used. See the <u>Session class</u> for more information on launching a graph and on sessions.

```
v = tf.Variable([1, 2])
init = tf.initialize_all_variables()

with tf.Session() as sess:
    sess.run(init)
    # Usage passing the session explicitly.
    print(v.eval(sess))
    # Usage with the default session. The 'with' block
    # above makes 'sess' the default session.
    print(v.eval())
```

Args:

 session: The session to use to evaluate this variable. If none, the default session is used.

Returns:

A numpy ndarray with a copy of the value of this variable.

Properties.

The name of this variable.
tf.Variable.dtype
The DType of this variable.
tf.Variable.get_shape()
The TensorShape of this variable.
Returns:
A TensorShape.
tf.Variable.device
The device of this variable.
tf.Variable.initializer
The initializer operation for this variable.

The Graph of this variable.

tf.Variable.op
The Operation of this variable.

Other Methods

tf.Variable.from_proto(variable_def)

Returns a reference to this variable.

You usually do not need to call this method as all ops that need a reference to the variable call it automatically.

Returns is a Tensor which holds a reference to the variable. You can assign a new value to the variable by passing the tensor to an assign op. See value () if you want to get the value of the variable.

Returns:

A Tensor that is a reference to the variable.

```
tf.Variable.to proto()
```

Converts a Variable to a VariableDef protocol buffer.

Returns:

A VariableDef protocol buffer.

```
tf.Variable.value()
```

Returns the last snapshot of this variable.

You usually do not need to call this method as all ops that need the value of the variable call it automatically through

```
a convert to tensor() call.
```

Returns a Tensor which holds the value of the variable. You can not assign a new value to this tensor as it is not a reference to the variable. See ref () if you want to get a reference to the variable.

To avoid copies, if the consumer of the returned value is on the same device as the variable, this actually returns the live value of the variable, not a copy. Updates to the variable are seen by the consumer. If the consumer is on a different device it will get a copy of the variable.

Returns:

A Tensor containing the value of the variable.

Variable helper functions

TensorFlow provides a set of functions to help manage the set of variables collected in the graph.

```
tf.all variables()
```

Returns all variables collected in the graph.

The <code>Variable()</code> constructor automatically adds new variables to the graph collection <code>GraphKeys.VARIABLES</code>. This convenience function returns the contents of that collection.

Returns:

A list of Variable objects.

```
tf.trainable variables()
```

Returns all variables created with trainable=True.

When passed trainable=True, the Variable() constructor automatically adds new variables to the graph collection GraphKeys.TRAINABLE_VARIABLES. This convenience function returns the contents of that collection.

Returns:

A list of Variable objects.

```
tf.moving average variables()
```

Returns all variables that maintain their moving averages.

If an Exponential Moving Average object is created and

the apply() method is called on a list of variables, these variables will be added to

the GraphKeys.MOVING_AVERAGE_VARIABLES collection. This convenience function returns the contents of that collection.

Returns:

A list of Variable objects.

```
tf.initialize_all_variables()
```

Returns an Op that initializes all variables.

This is just a shortcut

```
for initialize variables(all variables())
```

Returns:

An Op that initializes all variables in the graph.

```
tf.initialize_variables(var list, name='init')
```

Returns an Op that initializes a list of variables.

After you launch the graph in a session, you can run the returned Op to initialize all the variables in var_list. This Op runs all the initializers of the variables in var_list in parallel.

Calling initialize_variables() is equivalent to passing the list of initializers to Group().

If var_list is empty, however, the function still returns an Op that can be run. That Op just has no effect.

Args:

- var list: List of Variable objects to initialize.
- name: Optional name for the returned operation.

Returns:

An Op that run the initializers of all the specified variables.

```
tf.assert_variables_initialized(var_list=None)
```

Returns an Op to check if variables are initialized.

When run, the returned Op will raise the exception FailedPreconditionError if any of the variables has not yet been initialized.

Note: This function is implemented by trying to fetch the values of the variables. If one of the variables is not initialized a message may be logged by the C++ runtime. This is expected.

var_list: List of Variable objects to check. Defaults to the value
 of all variables().

Returns:

An Op, or None if there are no variables.

Saving and Restoring Variables

```
class tf.train.Saver
```

Saves and restores variables.

See <u>Variables</u> for an overview of variables, saving and restoring.

The saver class adds ops to save and restore variables to and from checkpoints. It also provides convenience methods to run these ops.

Checkpoints are binary files in a proprietary format which map variable names to tensor values. The best way to examine the contents of a checkpoint is to load it using a Saver.

Savers can automatically number checkpoint filenames with a provided counter. This lets you keep multiple checkpoints at different steps while training a model. For example you can number the checkpoint filenames with the training step number. To avoid filling up disks, savers manage checkpoint files automatically. For example, they can keep only the N most recent files, or one checkpoint for every N hours of training.

You number checkpoint filenames by passing a value to the optional global step argument to save():

```
saver.save(sess, 'my-model', global_step=0) ==> filename: 'my-
model-0'
```

```
saver.save(sess, 'my-model', global_step=1000) ==> filename: 'my-
model-1000'
```

Additionally, optional arguments to the <code>Saver()</code> constructor let you control the proliferation of checkpoint files on disk:

- max_to_keep indicates the maximum number of recent checkpoint files to keep. As new files are created, older files are deleted. If None or 0, all checkpoint files are kept. Defaults to 5 (that is, the 5 most recent checkpoint files are kept.)
- keep_checkpoint_every_n_hours: In addition to keeping the most recent max_to_keep checkpoint files, you might want to keep one checkpoint file for every N hours of training. This can be useful if you want to later analyze how a model progressed during a long training session. For example,

passingkeep_checkpoint_every_n_hours=2 ensures that you keep one checkpoint file for every 2 hours of training. The default value of 10,000 hours effectively disables the feature.

Note that you still have to call the <code>save()</code> method to save the model. Passing these arguments to the constructor will not save variables automatically for you.

A training program that saves regularly looks like:

```
# Create a saver.
saver = tf.train.Saver(...variables...)
# Launch the graph and train, saving the model every 1,000 steps.
sess = tf.Session()
for step in xrange(10000000):
    sess.run(..training_op..)
    if step % 1000 == 0:
        # Append the step number to the checkpoint name:
        saver.save(sess, 'my-model', global step=step)
```

In addition to checkpoint files, savers keep a protocol buffer on disk with the list of recent checkpoints. This is used to manage numbered checkpoint files and by <code>latest_checkpoint()</code>, which makes it easy to discover the path to the most recent checkpoint. That protocol

buffer is stored in a file named 'checkpoint' next to the checkpoint files.

If you create several savers, you can specify a different filename for the protocol buffer file in the call to save().

```
tf.train.Saver.__init__(var_list=None, reshape=False,
sharded=False, max_to_keep=5,
keep_checkpoint_every_n_hours=10000.0, name=None,
restore_sequentially=False, saver_def=None, builder=None)
Creates a Saver.
```

The constructor adds ops to save and restore variables.

var_list specifies the variables that will be saved and restored. It
can be passed as a dict or a list:

- A dict of names to variables: The keys are the names that will be used to save or restore the variables in the checkpoint files.
- A list of variables: The variables will be keyed with their op name in the checkpoint files.

For example:

```
v1 = tf.Variable(..., name='v1')
v2 = tf.Variable(..., name='v2')

# Pass the variables as a dict:
saver = tf.train.Saver({'v1': v1, 'v2': v2})

# Or pass them as a list.
saver = tf.train.Saver([v1, v2])
# Passing a list is equivalent to passing a dict with the variable op names
# as keys:
saver = tf.train.Saver({v.op.name: v for v in [v1, v2]})
```

The optional reshape argument, if True, allows restoring a variable from a save file where the variable had a different shape, but the same number of elements and type. This is useful if you have reshaped a variable and want to reload it from an older checkpoint.

The optional sharded argument, if True, instructs the saver to shard checkpoints per device.

Args:

- var_list: A list of Variable objects or a dictionary mapping names
 to variables. If None, defaults to the list of all variables.
- reshape: If True, allows restoring parameters from a checkpoint where the variables have a different shape.
- sharded: If True, shard the checkpoints, one per device.
- max_to_keep: Maximum number of recent checkpoints to keep.
 Defaults to 5.
- keep_checkpoint_every_n_hours: How often to keep checkpoints.
 Defaults to 10,000 hours.
- name: String. Optional name to use as a prefix when adding operations.
- restore_sequentially: A Bool, which if true, causes restore of different variables to happen sequentially within each device. This can lower memory usage when restoring very large models.
- saver_def: Optional SaverDef proto to use instead of running the builder. This is only useful for specialty code that wants to recreate a Saver object for a previously built Graph that had a Saver.

The saver_defproto should be the one returned by the as saver def() call of the Saver that was created for that Graph.

builder: Optional SaverBuilder to use if a saver_def was not
 provided. Defaults toBaseSaverBuilder().

Raises:

- TypeError: If var list is invalid.
- ValueError: If any of the keys or values in var list are not unique.

```
tf.train.Saver.save(sess, save_path, global_step=None,
latest filename=None, meta graph suffix='meta')
```

Saves variables.

This method runs the ops added by the constructor for saving variables. It requires a session in which the graph was launched. The variables to save must also have been initialized.

The method returns the path of the newly created checkpoint file. This path can be passed directly to a call torestore().

- sess: A Session to use to save the variables.
- save_path: String. Path to the checkpoint filename. If the saver
 is sharded, this is the prefix of the sharded checkpoint filename.
- global_step: If provided the global step number is appended to save_path to create the checkpoint filename. The optional argument can be a Tensor, a Tensor name or an integer.

- latest_filename: Optional name for the protocol buffer file that will
 contains the list of most recent checkpoint filenames. That file, kept in
 the same directory as the checkpoint files, is automatically managed
 by the saver to keep track of recent checkpoints. Defaults to
 'checkpoint'.
- meta graph suffix: Suffix for MetaGraphDef file. Defaults to 'meta'.

Returns:

A string: path at which the variables were saved. If the saver is sharded, this string ends with: '-?????-of-nnnnn' where 'nnnnn' is the number of shards created.

Raises:

- TypeError: If sess is not a Session.
- ValueError: If latest filename contains path components.

```
tf.train.Saver.restore(sess, save path)
```

Restores previously saved variables.

This method runs the ops added by the constructor for restoring variables. It requires a session in which the graph was launched. The variables to restore do not have to have been initialized, as restoring is itself a way to initialize variables.

The save_path argument is typically a value previously returned from

```
a save() call, or a call to latest checkpoint().
```

- sess: A Session to use to restore the parameters.
- save path: Path where parameters were previously saved.

Other utility methods.

```
tf.train.Saver.last checkpoints
```

List of not-yet-deleted checkpoint filenames.

You can pass any of the returned values to restore().

Returns:

A list of checkpoint filenames, sorted from oldest to newest.

```
tf.train.Saver.set last checkpoints(last checkpoints)
```

DEPRECATED: Use set_last_checkpoints_with_time.

Sets the list of old checkpoint filenames.

Args:

last checkpoints: A list of checkpoint filenames.

Raises:

• AssertionError: If last_checkpoints is not a list.

```
tf.train.Saver.as saver def()
Generates a SaverDef representation of this saver.
Returns:
A SaverDef proto.
Other Methods
tf.train.Saver.export meta graph(filename=None,
collection list=None, as text=False)
Writes MetaGraphDef to save_path/filename.
Args:
filename: Optional meta_graph filename including the path.
collection_list: List of string keys to collect.
as text: If True, writes the meta_graph as an ASCII proto.
Returns:
```

A MetaGraphDef proto.

```
tf.train.Saver.from proto(saver def)
  tf.train.Saver.set last checkpoints with time(last checkp
  oints with time)
  Sets the list of old checkpoint filenames and timestamps.
  Args:
 last checkpoints with time: A list of tuples of checkpoint
  filenames and timestamps.
  Raises:
• AssertionError: If last_checkpoints_with_time is not a list.
  tf.train.Saver.to proto()
  Returns a SaverDef protocol buffer.
  tf.train.latest checkpoint(checkpoint dir,
  latest filename=None)
  Finds the filename of latest saved checkpoint file.
```

• checkpoint dir: Directory where the variables were saved.

 latest_filename: Optional name for the protocol buffer file that contains the list of most recent checkpoint filenames. See the corresponding argument to Saver.save().

Returns:

The full path to the latest checkpoint or None if no checkpoint was found.

```
tf.train.get_checkpoint_state(checkpoint_dir,
latest_filename=None)
```

Returns CheckpointState proto from the "checkpoint" file.

If the "checkpoint" file contains a valid CheckpointState proto, returns it.

Args:

- checkpoint_dir: The directory of checkpoints.
- latest_filename: Optional name of the checkpoint file. Default to 'checkpoint'.

Returns:

A CheckpointState if the state was available, None otherwise.

```
tf.train.update_checkpoint_state(save_dir,
model_checkpoint_path, all_model_checkpoint_paths=None,
latest filename=None)
```

Updates the content of the 'checkpoint' file.

This updates the checkpoint file containing a CheckpointState proto.

Args:

- save dir: Directory where the model was saved.
- model checkpoint path: The checkpoint file.
- all_model_checkpoint_paths: List of strings. Paths to all not-yetdeleted checkpoints, sorted from oldest to newest. If this is a nonempty list, the last element must be equal to model_checkpoint_path. These paths are also saved in the CheckpointState proto.
- latest_filename: Optional name of the checkpoint file. Default to 'checkpoint'.

Raises:

• RuntimeError: If the save paths conflict.

Sharing Variables

TensorFlow provides several classes and operations that you can use to create variables contingent on certain conditions.

```
tf.get_variable(name, shape=None, dtype=tf.float32,
initializer=None, trainable=True, collections=None)
```

Gets an existing variable with these parameters or create a new one.

This function prefixes the name with the current variable scope and performs reuse checks. See the <u>Variable Scope How To</u> for an extensive description of how reusing works. Here is a basic example:

```
with tf.variable_scope("foo"):
    v = tf.get_variable("v", [1]) # v.name == "foo/v:0"
    w = tf.get_variable("w", [1]) # w.name == "foo/w:0"
with tf.variable_scope("foo", reuse=True)
    v1 = tf.get_variable("v") # The same as v above.
```

If initializer is None (the default), the default initializer passed in the constructor is used. If that one is None too,

auniformUnitScalingInitializer will be used. The initializer can also be a Tensor, in which case the variable is initialized to this value and shape.

Args:

- name: the name of the new or existing variable.
- shape: shape of the new or existing variable.
- dtype: type of the new or existing variable (defaults to DT_FLOAT).
- initializer: initializer for the variable if one is created.
- trainable: If True also add the variable to the graph
 collection GraphKeys.TRAINABLE_VARIABLES(see tf.Variable).
- collections: List of graph collections keys to add the Variable to.
 Defaults to [GraphKeys.VARIABLES] (see tf.Variable).

Returns:

The created or existing variable.

Raises:

 ValueError: when creating a new variable and shape is not declared, or when violating reuse during variable creation. Reuse is set inside variable scope.

```
tf.get variable scope()
```

Returns the current variable scope.

```
tf.make template(name , func , **kwargs)
```

Given an arbitrary function, wrap it so that it does variable sharing.

This wraps <code>func_</code> in a Template and partially evaluates it. Templates are functions that create variables the first time they are called and reuse them thereafter. In order for <code>func_</code> to be compatible with a <code>Template</code> it must have the following properties:

- The function should create all trainable variables and any variables that should be reused by callingtf.get_variable. If a trainable variable is created using tf.Variable, then a ValueError will be thrown. Variables that are intended to be locals can be created by specifying tf.Variable(..., trainable=false).
- The function may use variable scopes and other templates internally
 to create and reuse variables, but it shouldn't
 use tf.get_variables to capture variables that are defined outside
 of the scope of the function.
- Internal scopes and variable names should not depend on any arguments that are not supplied tomake template. In general you will

get a ValueError telling you that you are trying to reuse a variable that doesn't exist if you make a mistake.

In the following example, both z and w will be scaled by the same y. It is important to note that if we didn't assignscalar_name and used a different name for z and w that a valueError would be thrown because it couldn't reuse the variable.

As a safe-guard, the returned function will raise a ValueError after the first call if trainable variables are created by calling tf.Variable.

If all of these are true, then 2 properties are enforced by the template:

- 1. Calling the same template multiple times will share all non-local variables.
- 2. Two different templates are guaranteed to be unique, unless you reenter the same variable scope as the initial definition of a template and redefine it. An examples of this exception:

```
# Creates a template that reuses the variables above.
with tf.variable_scope(vs, reuse=True):
    scale_by_y2 = tf.make_template('scale_by_y', my_op,
    scalar_name='y')
    z2 = scale_by_y2(input1)
    w2 = scale_by_y2(input2)
```

Note: The full variable scope is captured at the time of the first call.

Note: name_ and func_ have a following underscore to reduce the likelihood of collisions with kwargs.

Args:

- name_: A name for the scope created by this template. If necessary,
 the name will be made unique by appending N to the name.
- func_: The function to wrap.
- **kwargs: Keyword arguments to apply to func_.

Returns:

A function that will enter a <code>variable_scope</code> before calling <code>func_</code>. The first time it is called, it will create a non-reusing scope so that the variables will be unique. On each subsequent call, it will reuse those variables.

Raises:

ValueError: if the name is None.

```
tf.variable_op_scope(values, name, default_name,
initializer=None)
```

Returns a context manager for defining an op that creates variables.

This context manager validates that the given values are from the same graph, ensures that that graph is the default graph, and pushes a name scope and a variable scope.

If name is not None, it is used as is in the variable scope. If name is

None, then $default_name$ is used. In that case, if the same name has been previously used in the same scope, it will made unique be appending $\,\mathbb{N}$ to it.

This is intended to be used when defining generic ops and so reuse is always inherited.

For example, to define a new Python op called my op with vars:

```
def my_op_with_vars(a, b, name=None):
    with tf.variable_op_scope([a, b], name, "MyOp") as scope:
    a = tf.convert_to_tensor(a, name="a")
    b = tf.convert_to_tensor(b, name="b")
    c = tf.get_variable('c')
    # Define some computation that uses `a`, `b`, and `c`.
    return foo_op(..., name=scope)
```

- values: The list of Tensor arguments that are passed to the op function.
- name: The name argument that is passed to the op function, this name is not uniquified in the variable scope.
- default_name: The default name to use if the name argument is None,
 this name will be uniquified.
- initializer: A default initializer to pass to variable scope.

Returns:

A context manager for use in defining a Python op.

Raises:

- ValueError: when trying to reuse within a create scope, or create
 within a reuse scope, or if reuse is notNone or True.
- TypeError: when the types of some arguments are not appropriate.

```
tf.variable_scope(name_or_scope, reuse=None,
initializer=None)
```

Returns a context for variable scope.

Variable scope allows to create new variables and to share already created ones while providing checks to not create or share by accident. For details, see the <u>Variable Scope How To</u>, here we present only a few basic examples.

Simple example of how to create a new variable:

```
with tf.variable_scope("foo"):
    with tf.variable_scope("bar"):
    v = tf.get_variable("v", [1])
    assert v.name == "foo/bar/v:0"
```

Basic example of sharing a variable:

```
with tf.variable_scope("foo"):
    v = tf.get_variable("v", [1])
with tf.variable_scope("foo", reuse=True):
    v1 = tf.get_variable("v", [1])
assert v1 == v
```

Sharing a variable by capturing a scope and setting reuse:

```
with tf.variable_scope("foo") as scope:
    v = tf.get_variable("v", [1])
    scope.reuse_variables()
    v1 = tf.get_variable("v", [1])
assert v1 == v
```

To prevent accidental sharing of variables, we raise an exception when getting an existing variable in a non-reusing scope.

```
with tf.variable_scope("foo"):
    v = tf.get_variable("v", [1])
    v1 = tf.get_variable("v", [1])
    # Raises ValueError("... v already exists ...").
```

Similarly, we raise an exception when trying to get a variable that does not exist in reuse mode.

```
with tf.variable_scope("foo", reuse=True):
    v = tf.get_variable("v", [1])
# Raises ValueError("... v does not exists ...").
```

Note that the reuse flag is inherited: if we open a reusing scope, then all its sub-scopes become reusing as well.

Args:

- name_or_scope: string or VariableScope: the scope to open.
- reuse: True or None; if True, we go into reuse mode for this scope as well as all sub-scopes; if None, we just inherit the parent scope reuse.
- initializer: default initializer for variables within this scope.

Returns:

A scope that can be to captured and reused.

Raises:

- ValueError: when trying to reuse within a create scope, or create
 within a reuse scope, or if reuse is notNone or True.
- TypeError: when the types of some arguments are not appropriate.

```
tf.constant initializer(value=0.0, dtype=tf.float32)
```

Returns an initializer that generates tensors with a single value.

Args:

- value: A Python scalar. All elements of the initialized variable will be set to this value.
- dtype: The data type. Only floating point types are supported.

Returns:

An initializer that generates tensors with a single value.

Raises:

• ValueError: if dtype is not a floating point type.

```
tf.random_normal_initializer(mean=0.0, stddev=1.0,
seed=None, dtype=tf.float32)
```

Returns an initializer that generates tensors with a normal distribution.

Args:

- mean: a python scalar or a scalar tensor. Mean of the random values to generate.
- stddev: a python scalar or a scalar tensor. Standard deviation of the random values to generate.
- seed: A Python integer. Used to create random seeds.

See set random seed for behavior.

dtype: The data type. Only floating point types are supported.

Returns:

An initializer that generates tensors with a normal distribution.

Raises:

• ValueError: if dtype is not a floating point type.

```
tf.truncated_normal_initializer(mean=0.0, stddev=1.0,
seed=None, dtype=tf.float32)
```

Returns an initializer that generates a truncated normal distribution.

These values are similar to values from

a random_normal_initializer except that values more than two standard deviations from the mean are discarded and re-drawn. This is the recommended initializer for neural network weights and filters.

- mean: a python scalar or a scalar tensor. Mean of the random values to generate.
- stddev: a python scalar or a scalar tensor. Standard deviation of the random values to generate.
- seed: A Python integer. Used to create random seeds.

See set random seed for behavior.

• dtype: The data type. Only floating point types are supported.

Returns:

An initializer that generates tensors with a truncated normal distribution.

Raises:

• ValueError: if dtype is not a floating point type.

```
tf.random_uniform_initializer(minval=0.0, maxval=1.0,
seed=None, dtype=tf.float32)
```

Returns an initializer that generates tensors with a uniform distribution.

- minval: a python scalar or a scalar tensor. lower bound of the range of random values to generate.
- maxval: a python scalar or a scalar tensor. upper bound of the range of random values to generate.

seed: A Python integer. Used to create random seeds.

See set random seed for behavior.

• dtype: The data type. Only floating point types are supported.

Returns:

An initializer that generates tensors with a uniform distribution.

Raises:

• ValueError: if dtype is not a floating point type.

```
tf.uniform_unit_scaling_initializer(factor=1.0,
seed=None, dtype=tf.float32)
```

Returns an initializer that generates tensors without scaling variance.

When initializing a deep network, it is in principle advantageous to keep the scale of the input variance constant, so it does not explode or diminish by reaching the final layer. If the input is \times and the

operation x * w, and we want to initialize w uniformly at random, we need to pick w from

```
[-sqrt(3) / sqrt(dim), sqrt(3) / sqrt(dim)]
```

to keep the scale intact, where dim = W.shape[0] (the size of the input). A similar calculation for convolutional networks gives an analogous result with dim equal to the product of the first 3 dimensions. When nonlinearities are present, we need to multiply this by a constant factor. See Sussillo et al., 2014 (pdf) for deeper motivation, experiments and the calculation of constants. In section

2.3 there, the constants were numerically computed: for a linear layer it's 1.0, relu: ~1.43, tanh: ~1.15.

Args:

- factor: Float. A multiplicative factor by which the values will be scaled.
- seed: A Python integer. Used to create random seeds.

See set random seed for behavior.

dtype: The data type. Only floating point types are supported.

Returns:

An initializer that generates tensors with unit variance.

Raises:

ValueError: if dtype is not a floating point type.

```
tf.zeros initializer(shape, dtype=tf.float32)
```

An adaptor for zeros() to match the Initializer spec.

Sparse Variable Updates

The sparse update ops modify a subset of the entries in a dense <code>Variable</code>, either overwriting the entries or adding / subtracting a delta. These are useful for training embedding models and similar lookup-based networks, since only a small subset of embedding vectors change in any given step.

Since a sparse update of a large tensor may be generated automatically during gradient computation (as in the gradient of tf.gather), an IndexedSlices class is provided that encapsulates a set of sparse indices and values. IndexedSlices objects are detected and handled automatically by the optimizers in most cases.

```
tf.scatter_update(ref, indices, updates,
use locking=None, name=None)
```

Applies sparse updates to a variable reference.

This operation computes

```
# Scalar indices
ref[indices, ...] = updates[...]

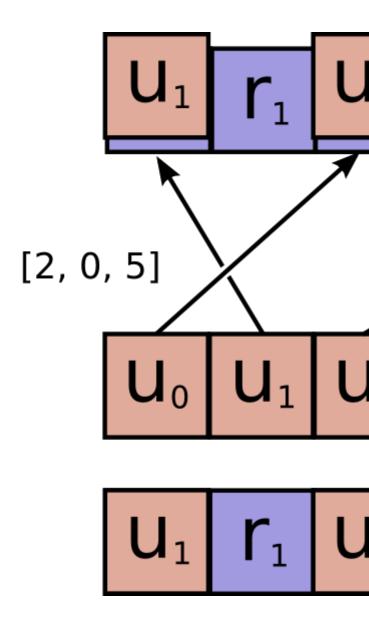

# Vector indices (for each i)
ref[indices[i], ...] = updates[i, ...]

# High rank indices (for each i, ..., j)
ref[indices[i, ..., j], ...] = updates[i, ..., j, ...]
```

This operation outputs ref after the update is done. This makes it easier to chain operations that need to use the reset value. If values in ref is to be updated more than once, because there are duplicate entires in indices, the order at which the updates happen for each value is undefined.

```
Requires updates.shape = indices.shape + ref.shape[1:].
```

ref indices updates

- ref: A mutable Tensor. Should be from a Variable node.
- indices: A Tensor. Must be one of the following types: int32, int64.
 A tensor of indices into the first dimension of ref.
- updates: A Tensor. Must have the same type as ref. A tensor of updated values to store in ref.

- use_locking: An optional bool. Defaults to True. If True, the
 assignment will be protected by a lock; otherwise the behavior is
 undefined, but may exhibit less contention.
- name: A name for the operation (optional).

Returns:

Same as ref. Returned as a convenience for operations that want to use the updated values after the update is done.

```
tf.scatter_add(ref, indices, updates, use_locking=None,
name=None)
```

Adds sparse updates to a variable reference.

This operation computes

```
# Scalar indices
ref[indices, ...] += updates[...]

# Vector indices (for each i)
ref[indices[i], ...] += updates[i, ...]

# High rank indices (for each i, ..., j)
ref[indices[i, ..., j], ...] += updates[i, ..., j, ...]
```

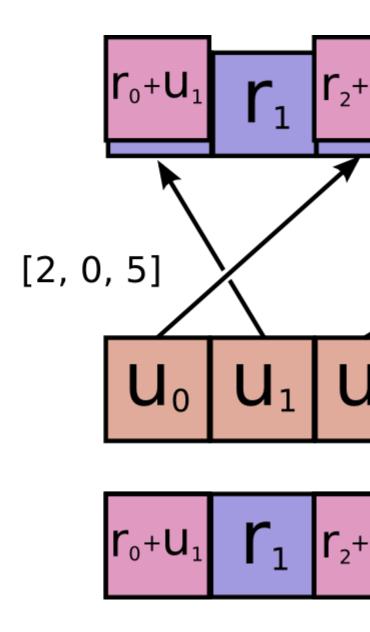

This operation outputs ref after the update is done. This makes it easier to chain operations that need to use the reset value.

Duplicate entries are handled correctly: if multiple indices reference the same location, their contributions add.

```
Requires updates.shape = indices.shape + ref.shape[1:].
```

ref indic

indices updates

Args:

ref: A mutable Tensor. Must be one of the following
 types: float32, float64, int64, int32, uint8, uint16, int16, int8,
 complex64, qint8, quint8, qint32. Should be from
 a Variable node.

indices: A Tensor. Must be one of the following types: int32, int64.
 A tensor of indices into the first dimension of ref.

- updates: A Tensor. Must have the same type as ref. A tensor of updated values to add to ref.
- use_locking: An optional bool. Defaults to False. If True, the addition will be protected by a lock; otherwise the behavior is undefined, but may exhibit less contention.
- name: A name for the operation (optional).

Returns:

Same as ref. Returned as a convenience for operations that want to use the updated values after the update is done.

```
tf.scatter_sub(ref, indices, updates, use_locking=None,
name=None)
```

Subtracts sparse updates to a variable reference.

```
# Scalar indices
ref[indices, ...] -= updates[...]

# Vector indices (for each i)
ref[indices[i], ...] -= updates[i, ...]

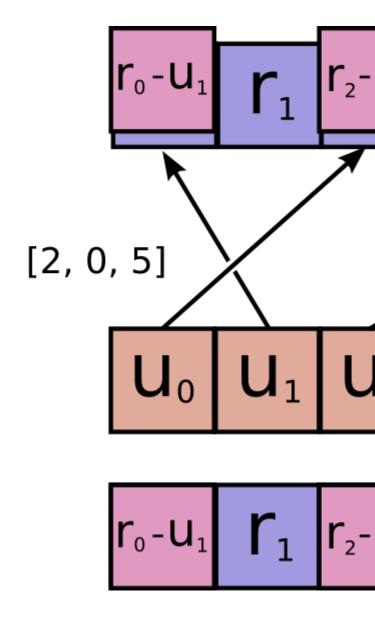

# High rank indices (for each i, ..., j)
ref[indices[i, ..., j], ...] -= updates[i, ..., j, ...]
```

This operation outputs ref after the update is done. This makes it easier to chain operations that need to use the reset value.

Duplicate entries are handled correctly: if multiple indices reference the same location, their (negated) contributions add.

```
Requires updates.shape = indices.shape + ref.shape[1:].
```

ref indices updates

Args:

ref: A mutable Tensor. Must be one of the following
 types: float32, float64, int64, int32, uint8, uint16, int16, int8,
 complex64, qint8, quint8, qint32. Should be from
 a Variable node.

indices: A Tensor. Must be one of the following types: int32, int64.
 A tensor of indices into the first dimension of ref.

- updates: A Tensor. Must have the same type as ref. A tensor of updated values to subtract from ref.
- use_locking: An optional bool. Defaults to False. If True, the subtraction will be protected by a lock; otherwise the behavior is undefined, but may exhibit less contention.
- name: A name for the operation (optional).

Returns:

Same as ref. Returned as a convenience for operations that want to use the updated values after the update is done.

```
tf.sparse_mask(a, mask_indices, name=None)
```

Masks elements of IndexedSlices.

Given an IndexedSlices instance a, returns

another IndexedSlices that contains a subset of the slices of a. Only

the slices at indices specified in mask_indices are returned.

This is useful when you need to extract a subset of slices in an IndexedSlices object.

For example:

```
# `a` contains slices at indices [12, 26, 37, 45] from a large
tensor
# with shape [1000, 10]
a.indices => [12, 26, 37, 45]
tf.shape(a.values) => [4, 10]

# `b` will be the subset of `a` slices at its second and third
indices, so
```

```
# we want to mask of its first and last indices (which are at
absolute
# indices 12, 45)
b = tf.sparse_mask(a, [12, 45])
b.indices => [26, 37]
tf.shape(b.values) => [2, 10]
```

Args:

- a: An IndexedSlices instance.
- mask_indices: Indices of elements to mask.
- name: A name for the operation (optional).

Returns:

The masked IndexedSlices instance.

```
class tf.IndexedSlices
```

A sparse representation of a set of tensor slices at given indices.

This class is a simple wrapper for a pair of Tensor objects:

- values: A Tensor of any dtype with shape [D0, D1, ..., Dn].
- indices: A 1-D integer Tensor with shape [D0].

An IndexedSlices is typically used to represent a subset of a larger tensor dense of shape [LARGEO, D1, ..., DN] where LARGEO >>

D0. The values in indices are the indices in the first dimension of the slices that have been extracted from the larger tensor.

The dense tensor dense represented by

an IndexedSlices slices has

```
dense[slices.indices[i], :, :, :, ...] =
slices.values[i, :, :, ...]
```

The IndexedSlices class is used principally in the definition of gradients for operations that have sparse gradients (e.g. tf.gather).

Contrast this representation with SparseTensor, which uses multidimensional indices and scalar values.

```
tf.IndexedSlices.__init__(values, indices,
dense_shape=None)
```

Creates an IndexedSlices.

tf.IndexedSlices.values

A Tensor containing the values of the slices.

tf.IndexedSlices.indices

A 1-D Tensor containing the indices of the slices.

tf.IndexedSlices.dense_shape
A 1-D Tensor containing the shape of the corresponding dense
tensor.
tf.IndexedSlices.name
The name of this IndexedSlices.
tf.IndexedSlices.dtype
The DType of elements in this tensor.
+6 TodougdClicos domino
The page of the device and which a will be produced and
The name of the device on which values will be produced, or None.
tf.IndexedSlices.op
The Operation that produces values as an output.
Other Methods
tf.IndexedSlices.graph

The Graph that contains the values, indices, and shape tensors.

Tensor Transformations

Note: Functions taking Tensor arguments can also take anything

```
accepted by tf.convert to tensor.
```

Casting

TensorFlow provides several operations that you can use to cast tensor data types in your graph.

```
tf.string_to_number(string_tensor, out_type=None,
name=None)
```

Converts each string in the input Tensor to the specified numeric type.

(Note that int32 overflow results in an error while float overflow results in a rounded value.)

Args:

- string_tensor: A Tensor of type string.
- out type: An optional tf.DType from: tf.float32, tf.int32.

Defaults to tf.float32. The numeric type to interpret each string in string_tensor as.

name: A name for the operation (optional).

A Tensor of type out_type. A Tensor of the same shape as the input string_tensor.

```
tf.to double(x, name='ToDouble')
```

Casts a tensor to type float 64.

Args:

- x: A Tensor **Or** SparseTensor.
- name: A name for the operation (optional).

Returns:

A Tensor or SparseTensor with same shape as x with type float64.

Raises:

• TypeError: If x cannot be cast to the float64.

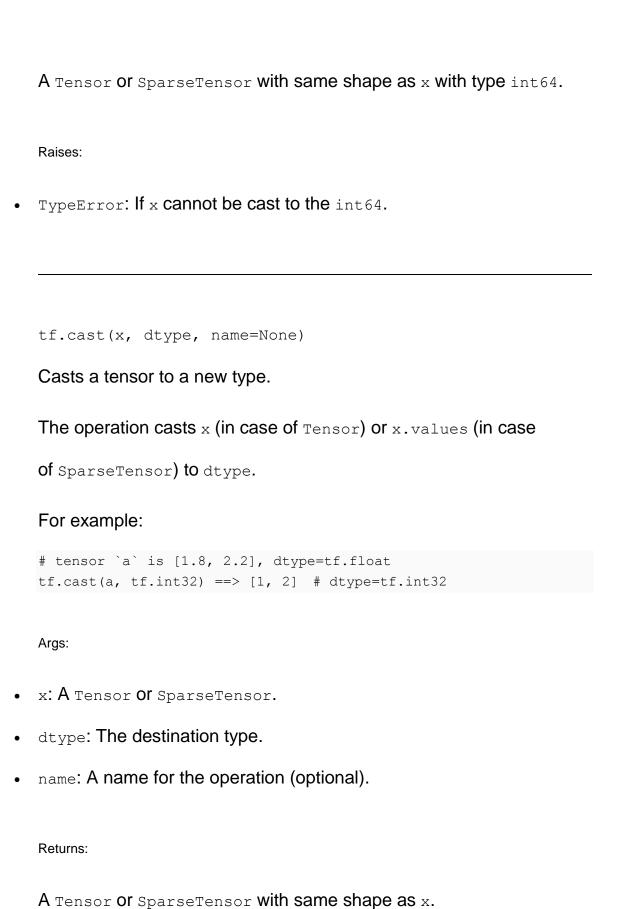

```
tf.to float(x, name='ToFloat')
```

Casts a tensor to type float32.

Args:

•	x: A Tensor Or SparseTensor.
•	name: A name for the operation (optional).
	Returns:
	A Tensor or SparseTensor with same shape as x with type float32.
	Raises:
•	TypeError: If x cannot be cast to the float32.
	tf.to_bfloat16(x, name='ToBFloat16')
	Casts a tensor to type bfloat16.
	Args:
•	x: A Tensor Of SparseTensor.
•	name: A name for the operation (optional).
	Returns:
	A Tensor or SparseTensor with same shape as x with type bfloat16.
	Raises:
•	TypeError: If x cannot be cast to the bfloat16.

```
tf.to int32(x, name='ToInt32')
  Casts a tensor to type int32.
   Args:
 x: A Tensor of SparseTensor.
 name: A name for the operation (optional).
   Returns:
  A Tensor or SparseTensor with same shape as x with type int32.
   Raises:
• TypeError: If x cannot be cast to the int32.
  tf.to_int64(x, name='ToInt64')
  Casts a tensor to type int64.
   Args:
 x: A Tensor Or SparseTensor.
• name: A name for the operation (optional).
   Returns:
```

Raises:

• TypeError: If x cannot be cast to the dtype.

Shapes and Shaping

TensorFlow provides several operations that you can use to determine the shape of a tensor and change the shape of a tensor.

```
tf.shape(input, name=None)
```

Returns the shape of a tensor.

This operation returns a 1-D integer tensor representing the shape of input.

For example:

```
# 't' is [[[1, 1, 1], [2, 2, 2]], [[3, 3, 3], [4, 4, 4]]] shape(t) ==> [2, 2, 3]
```

Args:

- input: A Tensor.
- name: A name for the operation (optional).

Returns:

A Tensor of type int32.

```
tf.size(input, name=None)
```

Returns the size of a tensor.

This operation returns an integer representing the number of elements in input.

For example:

```
# 't' is [[[1, 1,, 1], [2, 2, 2]], [[3, 3, 3], [4, 4, 4]]]]
size(t) ==> 12
```

Args:

- input: A Tensor.
- name: A name for the operation (optional).

Returns:

A Tensor of type int32.

```
tf.rank(input, name=None)
```

Returns the rank of a tensor.

This operation returns an integer representing the rank of input.

For example:

```
# 't' is [[[1, 1, 1], [2, 2, 2]], [[3, 3, 3], [4, 4, 4]]]
# shape of tensor 't' is [2, 2, 3]
rank(t) ==> 3
```

Note: The rank of a tensor is not the same as the rank of a matrix. The rank of a tensor is the number of indices required to uniquely

select each element of the tensor. Rank is also known as "order", "degree", or "ndims."

Args:

- input: A Tensor.
- name: A name for the operation (optional).

Returns:

A Tensor of type int32.

tf.reshape(tensor, shape, name=None)

Reshapes a tensor.

Given tensor, this operation returns a tensor that has the same values as tensor with shape shape.

If one component of shape is the special value -1, the size of that dimension is computed so that the total size remains constant. In particular, a shape of [-1] flattens into 1-D. At most one component of shape can be -1.

If shape is 1-D or higher, then the operation returns a tensor with shape shape filled with the values of tensor. In this case, the number of elements implied by shape must be the same as the number of elements in tensor.

For example:

```
# tensor 't' is [1, 2, 3, 4, 5, 6, 7, 8, 9]
# tensor 't' has shape [9]
reshape(t, [3, 3]) ==> [[1, 2, 3]
                    [4, 5, 6]
                    [7, 8, 9]]
# tensor 't' is [[[1, 1], [2, 2]]
              [[3, 3], [4, 4]]]
# tensor 't' has shape [2, 2, 2]
reshape(t, [2, 4]) ==> [[1, 1, 2, 2]
                    [3, 3, 4, 4]]
# tensor 't' is [[[1, 1, 1],
               [2, 2, 2]],
              [[3, 3, 3],
#
               [4, 4, 4]],
#
              [[5, 5, 5],
               [6, 6, 6]]]
# tensor 't' has shape [3, 2, 3]
# pass '[-1]' to flatten 't'
reshape(t, [-1]) ==> [1, 1, 1, 2, 2, 2, 3, 3, 3, 4, 4, 4, 5, 5,
5, 6, 6, 6]
\# -1 can also be used with higher dimensional shapes
reshape(t, [2, -1]) ==> [[1, 1, 1, 2, 2, 2, 3, 3, 3],
                     [4, 4, 4, 5, 5, 5, 6, 6, 6]]
# tensor 't' is [7]
# shape `[]` reshapes to a scalar
reshape(t, []) ==> 7
```

Args:

- tensor: A Tensor.
- shape: A Tensor of type int32. Defines the shape of the output tensor.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as tensor.

```
tf.squeeze(input, squeeze dims=None, name=None)
```

Removes dimensions of size 1 from the shape of a tensor.

Given a tensor input, this operation returns a tensor of the same type with all dimensions of size 1 removed. If you don't want to remove all size 1 dimensions, you can remove specific size 1 dimensions by specifyingsqueeze dims.

For example:

```
# 't' is a tensor of shape [1, 2, 1, 3, 1, 1]
shape(squeeze(t)) ==> [2, 3]
```

Or, to remove specific size 1 dimensions:

```
# 't' is a tensor of shape [1, 2, 1, 3, 1, 1]
shape(squeeze(t, [2, 4])) ==> [1, 2, 3, 1]
```

Args:

- input: A Tensor. The input to squeeze.
- squeeze_dims: An optional list of ints. Defaults to []. If specified,
 only squeezes the dimensions listed. The dimension index starts at 0.
 It is an error to squeeze a dimension that is not 1.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input. Contains the same data as input, but has one or more dimensions of size 1 removed.

```
tf.expand dims(input, dim, name=None)
```

Inserts a dimension of 1 into a tensor's shape.

Given a tensor input, this operation inserts a dimension of 1 at the dimension index dim of input's shape. The dimension

index dim starts at zero; if you specify a negative number for dim it is counted backward from the end.

This operation is useful if you want to add a batch dimension to a single element. For example, if you have a single image of shape [height, width, channels], you can make it a batch of 1 image withexpand_dims(image, 0), which will make the shape [1, height, width, channels].

Other examples:

```
# 't' is a tensor of shape [2]
shape(expand_dims(t, 0)) ==> [1, 2]
shape(expand_dims(t, 1)) ==> [2, 1]
shape(expand_dims(t, -1)) ==> [2, 1]

# 't2' is a tensor of shape [2, 3, 5]
shape(expand_dims(t2, 0)) ==> [1, 2, 3, 5]
shape(expand_dims(t2, 2)) ==> [2, 3, 1, 5]
shape(expand_dims(t2, 3)) ==> [2, 3, 5, 1]
```

This operation requires that:

```
-1-input.dims() <= dim <= input.dims()
```

This operation is related to squeeze(), which removes dimensions of size 1.

Args:

- input: A Tensor.
- dim: A Tensor of type int32. 0-D (scalar). Specifies the dimension index at which to expand the shape of input.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input. Contains the same data as input, but its shape has an additional dimension of size 1 added.

Slicing and Joining

TensorFlow provides several operations to slice or extract parts of a tensor, or join multiple tensors together.

```
tf.slice(input , begin, size, name=None)
```

Extracts a slice from a tensor.

This operation extracts a slice of size <code>size</code> from a tensor <code>input</code> starting at the location specified by <code>begin</code>. The slice <code>size</code> is represented as a tensor shape, where <code>size[i]</code> is the

number of elements of the 'i'th dimension of input that you want to slice. The starting location (begin) for the slice is represented as an offset in each dimension of input. In other words, begin[i] is the offset into the 'i'th dimension of input that you want to slice from.

begin is zero-based; size is one-based. If size[i] is -1, all remaining elements in dimension i are included in the slice. In other words, this is equivalent to setting:

```
size[i] = input.dim size(i) - begin[i]
```

This operation requires that:

```
0 \le \text{begin}[i] \le \text{begin}[i] + \text{size}[i] \le \text{Di for i in } [0, n]
```

For example:

Args:

- input : A Tensor.
- begin: An int32 or int64 Tensor.
- size: An int32 or int64 Tensor.
- name: A name for the operation (optional).

Returns:

A Tensor the same type as input.

```
tf.split(split_dim, num_split, value, name='split')

Splits a tensor into num_split tensors along one dimension.

Splits value along dimension split_dim into num_split smaller tensors. Requires that num_split evenly

divide value.shape[split_dim].
```

For example:

```
# 'value' is a tensor with shape [5, 30]
# Split 'value' into 3 tensors along dimension 1
split0, split1, split2 = tf.split(1, 3, value)
tf.shape(split0) ==> [5, 10]
```

Args:

- split_dim: A 0-D int32 Tensor. The dimension along which to split.
 Must be in the range [0, rank(value)).
- num split: A Python integer. The number of ways to split.
- value: The Tensor to split.
- name: A name for the operation (optional).

Returns:

 $\verb"num_split Tensor" \textbf{ objects resulting from splitting } \verb"value".$

```
tf.tile(input, multiples, name=None)
```

Constructs a tensor by tiling a given tensor.

This operation creates a new tensor by replicating input multiples times. The output tensor's i'th dimension has input.dims(i) * multiples[i] elements, and the values of input are replicated multiples[i] times along the 'i'th dimension.

For example, tiling [a b c d] by [2] produces [a b c d a b c d].

Args:

- input: A Tensor. 1-D or higher.
- multiples: A Tensor of type int32. 1-D. Length must be the same
 as the number of dimensions in input
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input.

```
tf.pad(input, paddings, name=None)
```

Pads a tensor with zeros.

This operation pads a input with zeros according to the paddings you specify. paddings is an integer tensor with shape [Dn, 2], where n is the rank of input. For each dimension D of input, paddings[D, 0] indicates how many zeros to add before the contents of input in that dimension, and paddings[D, 1] indicates how many zeros to add after the contents of input in that dimension.

The padded size of each dimension D of the output is:

```
paddings(D, 0) + input.dim size(D) + paddings(D, 1)
```

For example:

Args:

- input: A Tensor.
- paddings: A Tensor of type int32.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input.

```
tf.concat(concat dim, values, name='concat')
```

Concatenates tensors along one dimension.

Concatenates the list of tensors values along

```
dimension concat_dim. If values[i].shape = [D0, D1, ...

Dconcat_dim(i), ...Dn], the concatenated result has shape

[D0, D1, ... Rconcat_dim, ...Dn]
```

where

```
Rconcat_dim = sum(Dconcat_dim(i))
```

That is, the data from the input tensors is joined along the concat dim dimension.

The number of dimensions of the input tensors must match, and all dimensions except concat dim must be equal.

For example:

```
t1 = [[1, 2, 3], [4, 5, 6]]
t2 = [[7, 8, 9], [10, 11, 12]]
tf.concat(0, [t1, t2]) ==> [[1, 2, 3], [4, 5, 6], [7, 8, 9], [10,
11, 12]]
tf.concat(1, [t1, t2]) ==> [[1, 2, 3, 7, 8, 9], [4, 5, 6, 10, 11,
12]]
# tensor t3 with shape [2, 3]
# tensor t4 with shape [2, 3]
tf.shape(tf.concat(0, [t3, t4])) ==> [4, 3]
tf.shape(tf.concat(1, [t3, t4])) ==> [2, 6]
```

Args:

 concat_dim: 0-D int32 Tensor. Dimension along which to concatenate.

- values: A list of Tensor objects or a single Tensor.
- name: A name for the operation (optional).

Returns:

A Tensor resulting from concatenation of the input tensors.

```
tf.pack(values, name='pack')
```

Packs a list of rank-R tensors into one rank-(R+1) tensor.

Packs tensors in values into a tensor with rank one higher than each tensor in values and shape [len (values)] + values [0].shape.

The output satisfies output[i, ...] = values[i][...].

This is the opposite of unpack. The numpy equivalent is

```
tf.pack([x, y, z]) = np.asarray([x, y, z])
```

Args:

- values: A list of Tensor objects with the same shape and type.
- name: A name for this operation (optional).

Returns:

output: A packed Tensor with the same type as values.

```
tf.unpack(value, num=None, name='unpack')
Unpacks the outer dimension of a rank-R tensor into rank-(R-
```

Unpacks num tensors from value along the first dimension. If num is not specified (the default), it is inferred from value's shape.

If value.shape[0] is not known, ValueError is raised.

The ith tensor in output is the slice value[i, ...]. Each tensor in output has shape value.shape[1:].

This is the opposite of pack. The numpy equivalent is

```
tf.unpack(x, n) = list(x)
```

Args:

1) tensors.

- value: A rank R > 0 Tensor to be unpacked.
- num: An int. The first dimension of value. Automatically inferred
 if None (the default).
- name: A name for the operation (optional).

Returns:

The list of Tensor objects unpacked from value.

Raises:

• ValueError: If num is unspecified and cannot be inferred.

```
tf.reverse_sequence(input, seq_lengths, seq_dim,
batch dim=None, name=None)
```

Reverses variable length slices.

This op first slices input along the dimension batch_dim, and for each slice i, reverses the firstseq_lengths[i] elements along the dimension seq_dim.

The elements of seq_lengths must obey seq_lengths[i] < input.dims[seq_dim], and seq_lengths must be a vector of length input.dims[batch_dim].

The output slice i along dimension batch_dim is then given by input slice i, with the first seq_lengths[i] slices along dimension seq_dim reversed.

For example:

```
# Given this:
batch_dim = 0
seq_dim = 1
input.dims = (4, 8, ...)
seq_lengths = [7, 2, 3, 5]

# then slices of input are reversed on seq_dim, but only up to
seq_lengths:
output[0, 0:7, :, ...] = input[0, 7:0:-1, :, ...]
output[1, 0:2, :, ...] = input[1, 2:0:-1, :, ...]
output[2, 0:3, :, ...] = input[2, 3:0:-1, :, ...]
output[3, 0:5, :, ...] = input[3, 5:0:-1, :, ...]
# while entries past seq_lens are copied through:
output[0, 7:, :, ...] = input[0, 7:, :, ...]
output[1, 2:, :, ...] = input[1, 2:, :, ...]
```

```
output[2, 3:, :, ...] = input[2, 3:, :, ...]
output[3, 2:, :, ...] = input[3, 2:, :, ...]
```

In contrast, if:

```
# Given this:
batch dim = 2
seq dim = 0
input.dims = (8, ?, 4, ...)
seq lengths = [7, 2, 3, 5]
# then slices of input are reversed on seq dim, but only up to
seq lengths:
output[0:7, :, 0, :, ...] = input[7:0:-1, :, 0, :, ...]
output[0:2, :, 1, :, ...] = input[2:0:-1, :, 1, :, ...]
output[0:3, :, 2, :, ...] = input[3:0:-1, :, 2, :, ...]
output[0:5, :, 3, :, ...] = input[5:0:-1, :, 3, :, ...]
# while entries past seq lens are copied through:
output[7:, :, 0, :, ...] = input[7:, :, 0, :, ...]
output[2:, :, 1, :, ...] = input[2:, :, 1, :, ...]
output[3:, :, 2, :, ...] = input[3:, :, 2, :, ...]
output[2:, :, 3, :, ...] = input[2:, :, 3, :, ...]
```

Args:

- input: A Tensor. The input to reverse.
- seq_lengths: A Tensor of type int64. 1-D with

```
length input.dims(batch_dim) andmax(seq_lengths) <
input.dims(seq_dim)</pre>
```

- seq dim: An int. The dimension which is partially reversed.
- batch_dim: An optional int. Defaults to 0. The dimension along which reversal is performed.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input. The partially reversed input. It has the same shape as input.

```
tf.reverse(tensor, dims, name=None)
```

Reverses specific dimensions of a tensor.

Given a tensor, and a bool tensor dims representing the dimensions of tensor, this operation reverses each dimension i of tensor where dims[i] is True.

tensor can have up to 8 dimensions. The number of dimensions of tensor must equal the number of elements in dims. In other words:

```
rank(tensor) = size(dims)
```

For example:

```
# tensor 't' is [[[[ 0, 1, 2, 3],
                [ 4, 5, 6, 7],
                [ 8, 9, 10, 11]],
#
               [[12, 13, 14, 15],
               [16, 17, 18, 19],
                [20, 21, 22, 23]]]
# tensor 't' shape is [1, 2, 3, 4]
# 'dims' is [False, False, False, True]
reverse(t, dims) ==> [[[[ 3, 2, 1, 0],
                    [7, 6, 5, 4],
                    [ 11, 10, 9, 8]],
                   [[15, 14, 13, 12],
                    [19, 18, 17, 16],
                    [23, 22, 21, 20]]]
# 'dims' is [False, True, False, False]
```

Args:

- tensor: A Tensor. Must be one of the following
 types: uint8, int8, int32, bool, float32, float64. Up to 8-D.
- dims: A Tensor of type bool. 1-D. The dimensions to reverse.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as tensor. The same shape as tensor.

```
tf.transpose(a, perm=None, name='transpose')
```

Transposes a. Permutes the dimensions according to perm.

The returned tensor's dimension i will correspond to the input dimension perm[i]. If perm is not given, it is set to (n-1...0), where n

is the rank of the input tensor. Hence by default, this operation performs a regular matrix transpose on 2-D input Tensors.

For example:

```
# 'x' is [[1 2 3]
# [4 5 6]]
tf.transpose(x) ==> [[1 4]]
                [2 5]
                 [3 6]]
# Equivalently
tf.transpose(x, perm=[1, 0]) ==> [[1 4]
                            [2 5]
                            [3 6]]
\# 'perm' is more useful for n-dimensional tensors, for n > 2
# 'x' is [[[1 2 3]
          [4 5 6]]
          [[7 8 9]
          [10 11 12]]
# Take the transpose of the matrices in dimension-0
tf.transpose(b, perm=[0, 2, 1]) ==> [[[1 4]
                               [2 5]
                               [3 6]]
                               [[7 10]
                               [8 11]
                               [9 12]]
```

Args:

- a: A Tensor.
- perm: A permutation of the dimensions of a.
- name: A name for the operation (optional).

Returns:

A transposed Tensor.

```
tf.space to depth(input, block size, name=None)
```

SpaceToDepth for tensors of type T.

Rearranges blocks of spatial data, into depth. More specifically, this op outputs a copy of the input tensor where values from

the height and width dimensions are moved to the depth dimension.

The attrblock_size indicates the input block size and how the data is moved.

- Non-overlapping blocks of size block_size x block size are rearranged into depth at each location.
- The depth of the output tensor is input_depth * block_size *
 block size.
- The input tensor's height and width must be divisible by block_size.
 That is, assuming the input is in the shape: [batch, height,

```
width, depth], the shape of the output will be: [batch,
height/block_size, width/block_size,
depth*block_size*block_size]
```

This operation requires that the input tensor be of rank 4, and that block size be >=1 and a divisor of both the

input height and width.

This operation is useful for resizing the activations between convolutions (but keeping all data), e.g. instead of pooling. It is also useful for training purely convolutional models.

For example, given this input of shape [1, 2, 2, 1], and block_size of 2:

```
x = [[[[1], [2]], [3], [4]]]
```

This operation will output a tensor of shape [1, 1, 1, 4]:

```
[[[[1, 2, 3, 4]]]]
```

Here, the input has a batch of 1 and each batch element has shape [2, 2, 1], the corresponding output will have a single element (i.e. width and height are both 1) and will have a depth of 4 channels (1 * block_size * block_size). The output element shape is [1, 1, 4].

For an input tensor with larger depth, here of shape [1, 2, 2, 3], e.g.

```
x = [[[[1, 2, 3], [4, 5, 6]], [[7, 8, 9], [10, 11, 12]]]]
```

This operation, for block_size of 2, will return the following tensor of shape [1, 1, 1, 12]

```
[[[[1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12]]]]
```

Similarly, for the following input of shape [1 4 4 1], and a block size of 2:

```
x = [[ [1], [2], [5], [6]],
        [ [3], [4], [7], [8]],
        [ [9], [10], [13], [14]],
        [ [11], [12], [15], [16]]]
```

the operator will return the following tensor of shape [1 2 2 4]:

Args:

- input: A Tensor.
- block_size: An int. The size of the spatial block.
- name: A name for the operation (optional).

Returns:

```
tf.depth_to_space(input, block_size, name=None)
```

DepthToSpace for tensors of type T.

Rearranges data from depth into blocks of spatial data. This is the reverse transformation of SpaceToDepth. More specifically, this op outputs a copy of the input tensor where values from

the depth dimension are moved in spatial blocks to

the height and width dimensions. The attr block_size indicates the input block size and how the data is moved.

- Chunks of data of size block_size * block_size from depth are rearranged into non-overlapping blocks of size block_size x block_size
- The width the output tensor is input_depth * block_size, whereas
 the height is input height * block size.
- The depth of the input tensor must be divisible by block_size *
 block_size.

That is, assuming the input is in the shape: [batch, height,

```
width, depth], the shape of the output will be: [batch,
height*block_size, width*block_size,
depth/(block_size*block_size)]
```

This operation requires that the input tensor be of rank 4, and that block_size be >=1 and that block_size * block_size be a divisor of the input depth.

This operation is useful for resizing the activations between convolutions (but keeping all data), e.g. instead of pooling. It is also useful for training purely convolutional models.

For example, given this input of shape [1, 1, 1, 4], and a block size of 2:

```
x = [[[[1, 2, 3, 4]]]]
```

This operation will output a tensor of shape [1, 2, 2, 1]:

```
[[[[1], [2]],
[[3], [4]]]]
```

Here, the input has a batch of 1 and each batch element has shape [1, 1, 4], the corresponding output will have 2x2 elements

```
and will have a depth of 1 channel (1 = 4 / (block_size * block size)). The output element shape is [2, 2, 1].
```

For an input tensor with larger depth, here of shape [1, 1, 1, 12], e.g.

```
x = [[[[1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12]]]]
```

This operation, for block size of 2, will return the following tensor of shape [1, 2, 2, 3]

```
[[[[1, 2, 3], [4, 5, 6]],
[[7, 8, 9], [10, 11, 12]]]]
```

Similarly, for the following input of shape [1 2 2 4], and a block size of 2:

the operator will return the following tensor of shape [1 4 4 1]:

```
x = [[ [1], [2], [5], [6]],
        [ [3], [4], [7], [8]],
        [ [9], [10], [13], [14]],
        [ [11], [12], [15], [16]]]
```

Args:

- input: A Tensor.
- block_size: An int. The size of the spatial block, same as in Space2Depth.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input.

```
tf.gather(params, indices, validate_indices=None,
name=None)
```

Gather slices from params according to indices.

indices must be an integer tensor of any dimension (usually 0-D or

1-D). Produces an output tensor with shape indices.shape +

params.shape[1:] where:

```
# Scalar indices
output[:, ..., :] = params[indices, :, ... :]

# Vector indices
output[i, :, ..., :] = params[indices[i], :, ... :]

# Higher rank indices
output[i, ..., j, :, ... :] = params[indices[i, ...,
j], :, ..., :]
```

If indices is a permutation and len(indices) ==

```
params.shape[0] then this operation will
```

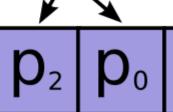

permuteparams accordingly.

params

 $p_0 | p_1 | p_2$

indices

[2, 0, 2, 5]

Args:

- params: A Tensor.
- indices: A Tensor. Must be one of the following types: int32, int64.
- validate_indices: An optional bool. Defaults to True.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as ${\tt params.}$

tf.dynamic_partition(data, partitions, num_partitions,
name=None)

Partitions data into num partitions tensors using indices

from partitions.

For each index tuple js of size partitions.ndim, the slice data[js, ...] becomes part of outputs[partitions[js]].

The slices with partitions[js] = i are placed in outputs[i] in lexicographic order of js, and the first dimension of outputs[i] is the number of entries in partitions equal to i. In detail,

```
outputs[i].shape = [sum(partitions == i)] +
data.shape[partitions.ndim:]
outputs[i] = pack([data[js, ...] for js if partitions[js] == i])
```

data.shape must start with partitions.shape.

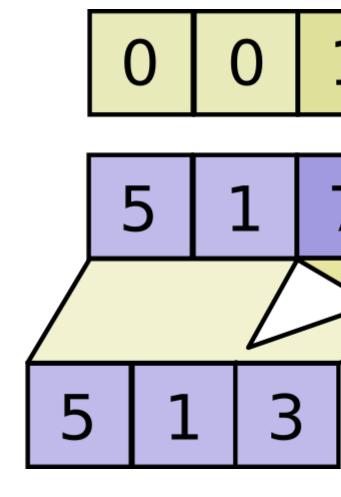

For example:

```
# Scalar partitions
partitions = 1
num_partitions = 2
data = [10, 20]
outputs[0] = [] # Empty with shape [0, 2]
outputs[1] = [[10, 20]]

# Vector partitions
partitions = [0, 0, 1, 1, 0]
num_partitions = 2
data = [10, 20, 30, 40, 50]
outputs[0] = [10, 20, 50]
outputs[1] = [30, 40]
```

partitions

data

Args:

- data: A Tensor.
- partitions: A Tensor of type int32. Any shape. Indices in the
 range [0, num_partitions).
- num_partitions: An int that is >= 1. The number of partitions to output.
- name: A name for the operation (optional).

Returns:

A list of num_partitions Tensor objects of the same type as data.

```
tf.dynamic stitch(indices, data, name=None)
```

Interleave the values from the data tensors into a single tensor.

Builds a merged tensor such that

```
merged[indices[m][i, ..., j], ...] = data[m][i, ..., j, ...]
```

For example, if each indices [m] is scalar or vector, we have

```
# Scalar indices
merged[indices[m], ...] = data[m][...]

# Vector indices
merged[indices[m][i], ...] = data[m][i, ...]
```

Each data[i].shape must start with the

corresponding indices[i].shape, and the rest

ofdata[i].shape must be constant w.r.t. i. That is, we must

have data[i].shape = indices[i].shape + constant. In terms of

this constant, the output shape is

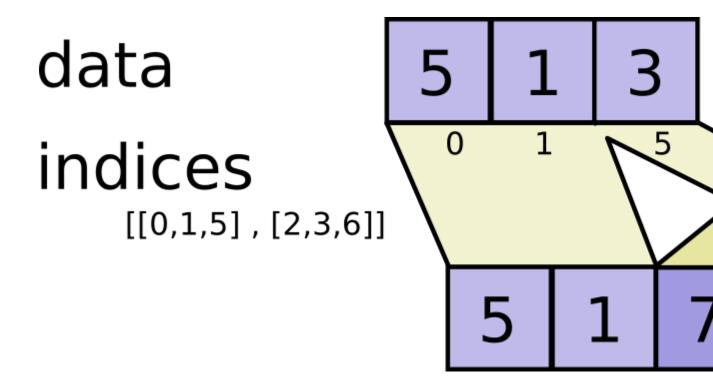

```
merged.shape = [max(indices)] + constant
```

Values are merged in order, so if an index appears in

```
both indices[m][i] and indices[n][j] for (m,i) < (n,j) the
```

slice data[n][j] will appear in the merged result.

For example:

Args:

- indices: A list of at least 2 Tensor objects of type int32.
- data: A list with the same number of Tensor objects
 as indices of Tensor objects of the same type.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as data.

tf.boolean mask(tensor, mask, name='boolean mask')

Apply boolean mask to tensor. Numpy equivalent is tensor [mask].

1-D example

```
tensor = [0, 1, 2, 3]
mask = [True, False, True, False]
boolean_mask(tensor, mask) ==> [0, 2]
```

In general, 0 < dim(mask) = K <= dim(tensor), and mask's shape must match the first K dimensions of tensor's shape. We then

```
have: boolean_mask(tensor, mask)[i, j1,...,jd] =
tensor[i1,...,iK,j1,...,jd] where (i1,...,iK) is the
ith True entry of mask (row-major order).
```

Args:

- tensor: N-D tensor. First K dimensions can be None, which allows
 e.g. undefined batch size. Trailing dimensions must be specified.
- mask: K-D boolean tensor, K <= N.
- name: A name for this operation (optional).

Returns:

Tensor populated by entries in tensor corresponding to True values in mask.

Raises:

- ValueError: If shapes do not conform.
- Examples: ```python

2-D example

```
a = [[1, 2], [3, 4], [5, 6]] mask = [True, False, True] boolean_mask(tensor, mask) ==> [[1, 2], [5, 6]] ```
```

Other Functions and Classes

```
tf.shape n(input, name=None)
```

Returns shape of tensors.

This operation returns N 1-D integer tensors representing shape of input[i]s.

Args:

- input: A list of at least 1 Tensor objects of the same type.
- name: A name for the operation (optional).

Returns:

A list with the same number of Tensor objects as input of Tensor objects of type int32.

```
tf.unique with counts(x, name=None)
```

Finds unique elements in a 1-D tensor.

This operation returns a tensor y containing all of the unique elements of x sorted in the same order that they occur in x. This operation also returns a tensor idx the same size as x that contains

the index of each value of xin the unique output y. Finally, it returns a third tensor count that contains the count of each element of y in x. In other words:

```
y[idx[i]] = x[i] for i in [0, 1,...,rank(x) - 1]
```

For example:

```
# tensor 'x' is [1, 1, 2, 4, 4, 4, 7, 8, 8]
y, idx, count = unique_with_counts(x)
y ==> [1, 2, 4, 7, 8]
idx ==> [0, 0, 1, 2, 2, 2, 3, 4, 4]
count ==> [2, 1, 3, 1, 2]
```

Args:

- x: A Tensor. 1-D.
- name: A name for the operation (optional).

Returns:

A tuple of Tensor objects (y, idx, count).

- y: A Tensor. Has the same type as x. 1-D.
- idx: A Tensor of type int32. 1-D.
- count: A Tensor of type int32. 1-D.

Math

Note: Functions taking Tensor arguments can also take anything accepted by tf.convert to tensor.

Arithmetic Operators

TensorFlow provides several operations that you can use to add basic arithmetic operators to your graph.

```
tf.add(x, y, name=None)
```

Returns x + y element-wise.

NOTE: Add supports broadcasting. AddN does not.

x: A Tensor. Must be one of the following
 types: float32, float64, uint8, int8, int16, int32, int64, complex
 64, string.

- y: A Tensor. Must have the same type as x.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as x.

tf.sub(x, y, name=None)

Returns x - y element-wise.

Args:

• x: A Tensor. Must be one of the following

types: float32, float64, int32, complex64, int64.

- y: A Tensor. Must have the same type as \mathbf{x} .
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as \mathbf{x} .

```
tf.mul(x, y, name=None)
```

Returns x * y element-wise.

Args:

• x: A Tensor. Must be one of the following

types: float32, float64, uint8, int8, int16, int32, int64, complex
64.

- y: A Tensor. Must have the same type as x.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as x.

```
tf.div(x, y, name=None)
```

Returns x / y element-wise.

Args:

• x: A Tensor. Must be one of the following

types: float32, float64, uint8, int8, int16, int32, int64, complex
64.

- y: A Tensor. Must have the same type as x.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as x.

```
tf.truediv(x, y, name=None)
```

Divides x / y elementwise, always producing floating point results.

The same as tf.div for floating point arguments, but casts integer arguments to floating point before dividing so that the result is always floating point. This op is generated by normal $x \neq y$ division in

```
Python 3 and in Python 2.7 with from __future__ import division. If you want integer division that rounds down, use x // yor tf.floordiv.
```

 $_{\rm X}$ and $_{\rm Y}$ must have the same numeric type. If the inputs are floating point, the output will have the same type. If the inputs are integral, the inputs are cast

to float32 for int8 and int16 and float64 for int32 and int64(mat ching the behavior of Numpy).

Args:

- x: Tensor numerator of numeric type.
- y: Tensor denominator of numeric type.
- name: A name for the operation (optional).

Returns:

x / y evaluated in floating point.

Raises:

TypeError: If x and y have different dtypes.

```
tf.floordiv(x, y, name=None)
```

Divides x / y elementwise, rounding down for floating point.

The same as tf.div(x,y) for integers, but

uses tf.floor(tf.div(x,y)) for floating point arguments so that the result is always an integer (though possibly an integer represented as floating point). This op is generated by x // y floor division in Python 3 and in Python 2.7 with from __future__ import division.

Note that for efficiency, floordiv uses C semantics for negative numbers (unlike Python and Numpy). $_{\rm X}$ and $_{\rm Y}$ must have the same type, and the result will have the same

Args:

type as well.

- x: Tensor numerator of real numeric type.
- y: Tensor denominator of real numeric type.
- name: A name for the operation (optional).

Returns:

 \times / $\ensuremath{\mathtt{y}}$ rounded down (except possibly towards zero for negative integers).

Raises:

• TypeError: If the inputs are complex.

```
tf.mod(x, y, name=None)
```

Returns element-wise remainder of division.

Args:

• x: A Tensor. Must be one of the following

types: int32, int64, float32, float64.

- y: A Tensor. Must have the same type as x.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as x.

```
tf.cross(a, b, name=None)
```

Compute the pairwise cross product.

a and b must be the same shape; they can either be simple 3element vectors, or any shape where the innermost dimension is 3. In the latter case, each pair of corresponding 3-element vectors is cross-multiplied independently.

Args:

• a: A Tensor. Must be one of the following

types: float32, float64, int32, int64, uint8, int16, int8, uint16. A tensor containing 3-element vectors.

- b: A Tensor. Must have the same type as a. Another tensor, of same type and shape as a.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as a. Pairwise cross product of the vectors in a and b.

Basic Math Functions

TensorFlow provides several operations that you can use to add basic mathematical functions to your graph.

tf.add n(inputs, name=None)

Add all input tensors element wise.

Args:

- inputs: A list of at least 1 Tensor objects of the same type

 in: float32, float64, int64, int32, uint8, uint16, int16, int8, com

 plex64, qint8, quint8, qint32. Must all be the same size and shape.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as inputs.

```
tf.abs(x, name=None)
```

Computes the absolute value of a tensor.

Given a tensor of real numbers x, this operation returns a tensor containing the absolute value of each element inx. For example, if x is an input element and y is an output element, this operation computes y=|x|y=|x|.

See tf.complex_abs() to compute the absolute value of a complex number.

- x: A Tensor of type float, double, int32, or int64.
- name: A name for the operation (optional).

_					
D	a	tı ı	rr	าร	•
ı	ᄝ	ւս	11	10	

A ${\tt Tensor}$ the same size and type as ${\tt x}$ with absolute values.

```
tf.neg(x, name=None)
```

Computes numerical negative value element-wise.

I.e.,
$$y=-xy=-x$$
.

Args:

• x: A Tensor. Must be one of the following

types: float32, float64, int32, complex64, int64.

• name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as \mathbf{x} .

```
tf.sign(x, name=None)
```

Returns an element-wise indication of the sign of a number.

$$y = sign(x) = -1 \text{ if } x < 0; 0 \text{ if } x == 0; 1 \text{ if } x > 0.$$

•	x: A Tensor. Must be one of the following			
	types: float32, float64, int32, int64.			
•	name: A name for the operation (optional).			
	Returns:			
	A Tensor. Has the same type as x .			
	tf.inv(x, name=None)			
	Computes the reciprocal of x element-wise.			
	I.e., $y=1/xy=1/x$.			
	1.6., y=1/Ay=1/A.			
	Args:			
•	x: A Tensor. Must be one of the following			
	types: float32, float64, int32, complex64, int64.			
	name: A name for the operation (optional).			
•	name. A name for the operation (optional).			
	Returns:			
	A Handan Has the same type as :			
	A Tensor. Has the same type as x.			

Computes square of x element-wise.

```
I.e., y=x*x=x2y=x*x=x2.
```

Args:

x: A Tensor. Must be one of the following

```
types: float32, float64, int32, complex64, int64.
```

name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as x.

```
tf.round(x, name=None)
```

Rounds the values of a tensor to the nearest integer, element-wise.

For example:

```
# 'a' is [0.9, 2.5, 2.3, -4.4]
tf.round(a) ==> [ 1.0, 3.0, 2.0, -4.0 ]
```

Args:

- x: A Tensor of type float or double.
- name: A name for the operation (optional).

Returns:

A Tensor of same shape and type as x.

tf.sqrt(x, name=None)

Computes square root of x element-wise.

I.e., $y=x\sqrt{-x_{1/2}}y=x=x_{1/2}$.

Args:

• x: A Tensor. Must be one of the following

types: float32, float64, int32, complex64, int64.

name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as \mathbf{x} .

tf.rsqrt(x, name=None)

Computes reciprocal of square root of x element-wise.

I.e., $y=1/x\sqrt{y}=1/x$.

x: A Tensor. Must be one of the following

types: float32, float64, int32, complex64, int64.

name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as x.

```
tf.pow(x, y, name=None)
```

Computes the power of one value to another.

Given a tensor x and a tensor y, this operation computes xyxy for corresponding elements in x and y. For example:

```
# tensor 'x' is [[2, 2]], [3, 3]]
# tensor 'y' is [[8, 16], [2, 3]]
tf.pow(x, y) ==> [[256, 65536], [9, 27]]
```

Args:

- x: A Tensor of type float, double, int32, complex64, or int64.
- y: A Tensor of type float, double, int32, complex64, or int64.
- name: A name for the operation (optional).

Returns:

A Tensor.

tf.exp(x, name=None)

Computes exponential of x element-wise. $y=e_xy=e_x$.

Args:

x: A Tensor. Must be one of the following

types: float32, float64, int32, complex64, int64.

• name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as x.

tf.log(x, name=None)

Computes natural logarithm of x element-wise.

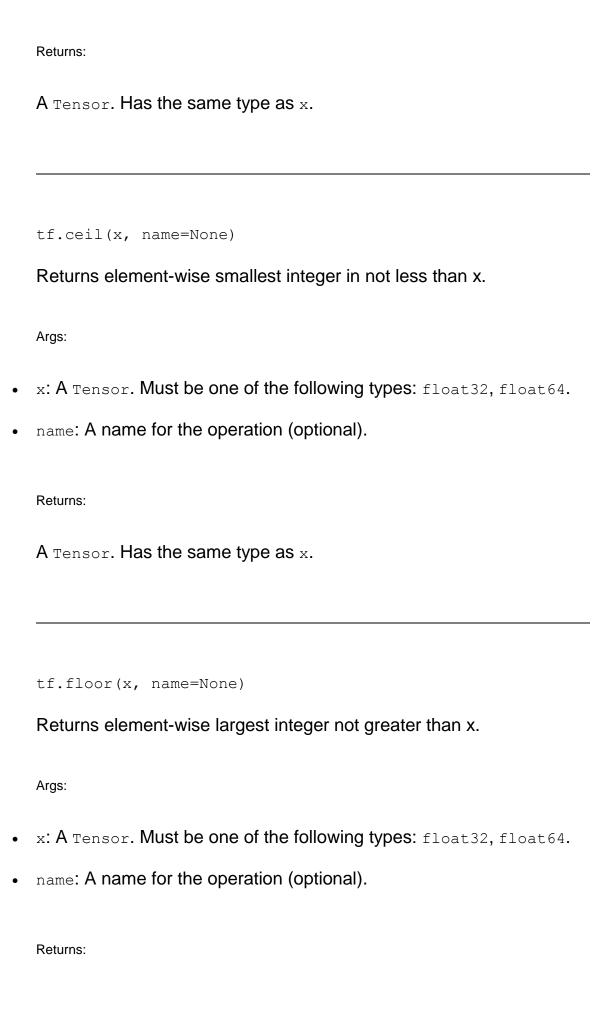

I.e., y=logexy=loge v.

Args:

• x: A Tensor. Must be one of the following

types: float32, float64, int32, complex64, int64.

name: A name for the operation (optional).

A Tensor. Has the same type as x.

```
tf.maximum(x, y, name=None)
```

Returns the max of x and y (i.e. x > y ? x : y) element-wise, broadcasts.

Args:

• x: A Tensor. Must be one of the following

types: float32, float64, int32, int64.

- y: A Tensor. Must have the same type as x.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as ${\tt x}$.

```
tf.minimum(x, y, name=None)
```

Returns the min of x and y (i.e. x < y ? x : y) element-wise, broadcasts.

•	x: A Tensor. Must be one of the following
	types: float32, float64, int32, int64.
•	y: A Tensor. Must have the same type as x.
•	name: A name for the operation (optional).
	Returns: A Tensor. Has the same type as $\mathbf x$.
	tf.cos(x, name=None)
	Computes cos of x element-wise.
	Args:
•	x: A Tensor. Must be one of the following
	types: float32, float64, int32, complex64, int64.
•	name: A name for the operation (optional).
	Returns: A Tensor. Has the same type as ${\tt x}$.
	tf.sin(x, name=None)

Computes sin of x element-wise. Args: x: A Tensor. Must be one of the following types: float32, float64, int32, complex64, int64. name: A name for the operation (optional). Returns: A Tensor. Has the same type as x. tf.lgamma(x, name=None) Computes ln(|gamma(x)|) element-wise. Args: x: A Tensor with type float, double, int32, int64, or qint32. name: A name for the operation (optional). Returns: A Tensor with the same type as x if x.dtype != qint32 otherwise

the return type is quint8.

```
tf.erf(x, name=None)
```

Computes Gauss error function of x element-wise.

Args:

- x: A Tensor with type float, double, int32, int64, or qint32.
- name: A name for the operation (optional).

Returns:

A Tensor with the same type as x if x.dtype != qint32 otherwise the return type is quint8.

```
tf.erfc(x, name=None)
```

Computes complementary error function of x element-wise.

Args:

- x: A Tensor with type float, double, int32, int64, or gint32.
- name: A name for the operation (optional).

Returns:

A Tensor with the same type as x if x.dtype != qint32 otherwise the return type is quint8.

Matrix Math Functions

TensorFlow provides several operations that you can use to add basic mathematical functions for matrices to your graph.

```
tf.diag(diagonal, name=None)
```

Returns a diagonal tensor with a given diagonal values.

Given a diagonal, this operation returns a tensor with

the diagonal and everything else padded with zeros. The diagonal is computed as follows:

Assume diagonal has dimensions [D1,..., Dk], then the output is a tensor of rank 2k with dimensions [D1,..., Dk, D1,..., Dk] where:

```
output[i1,..., ik, i1,..., ik] = diagonal[i1, ..., ik] and
0 everywhere else.
```

For example:

- diagonal: A Tensor. Must be one of the following
 types: float32, float64, int32, int64. Rank k tensor where k is at most 3.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as diagonal.

```
tf.transpose(a, perm=None, name='transpose')
```

Transposes a. Permutes the dimensions according to perm.

The returned tensor's dimension i will correspond to the input dimension perm[i]. If perm is not given, it is set to (n-1...0), where n is the rank of the input tensor. Hence by default, this operation performs a regular matrix transpose on 2-D input Tensors.

For example:

```
# 'x' is [[1 2 3]
        [4 5 6]]
tf.transpose(x) ==> [[1 4]]
                  [2 5]
                  [3 6]]
# Equivalently
tf.transpose(x, perm=[1, 0]) \Longrightarrow [[1 4]
                              [2 5]
                              [3 6]]
\# 'perm' is more useful for n-dimensional tensors, for n > 2
# 'x' is [[[1 2 3]
           [4 5 6]]
          [[7 8 9]
           [10 11 12]]
# Take the transpose of the matrices in dimension-0
tf.transpose(b, perm=[0, 2, 1]) ==> [[[1 4]
                                 [2 5]
                                 [3 6]]
                                [[7 10]
                                 [8 11]
                                 [9 12]]]
```

Args:

- a: A Tensor.
- perm: A permutation of the dimensions of a.
- name: A name for the operation (optional).

Returns:

A transposed Tensor.

```
tf.matmul(a, b, transpose_a=False, transpose_b=False,
a_is_sparse=False, b_is_sparse=False, name=None)
```

Multiplies matrix a by matrix b, producing a * b.

The inputs must be two-dimensional matrices, with matching inner dimensions, possibly after transposition.

Both matrices must be of the same type. The supported types

```
are: float, double, int32, complex64.
```

Either matrix can be transposed on the fly by setting the corresponding flag to True. This is False by default.

If one or both of the matrices contain a lot of zeros, a more efficient multiplication algorithm can be used by setting the

```
corresponding a_is_sparse or b_is_sparse flag to True. These are False by default.
```

For example:

```
# 2-D tensor `a`
a = tf.constant([1, 2, 3, 4, 5, 6], shape=[2, 3]) => [[1. 2. 3.]
[4. 5. 6.]]
```

Args:

- a: Tensor **of type** float, double, int32 **or** complex64.
- b: Tensor with same type as a.
- transpose a: If True, a is transposed before multiplication.
- transpose b: If True, b is transposed before multiplication.
- a is sparse: If True, a is treated as a sparse matrix.
- b is sparse: If True, b is treated as a sparse matrix.
- name: Name for the operation (optional).

Returns:

A Tensor of the same type as a.

```
tf.batch_matmul(x, y, adj_x=None, adj_y=None, name=None)
```

Multiplies slices of two tensors in batches.

Multiplies all slices of $Tensor \times and y$ (each slice can be viewed as an element of a batch), and arranges the individual results in a single output tensor of the same batch size. Each of the individual slices can optionally be adjointed (to adjoint a matrix means to transpose

and conjugate it) before multiplication by setting

the adj_x oradj_y flag to True, which are by default False.

The input tensors x and y are 3-D or higher with shape [..., r x,

```
c_x and [..., r_y, c_y].
```

The output tensor is 3-D or higher with shape [..., r_0 , c_0], where:

```
r_o = c_x if adj_x else r_x
c_o = r_y if adj_y else c_y
```

It is computed as:

```
out[..., :, :] = matrix(x[..., :, :]) * matrix(y[..., :, :])
```

Args:

• x: A Tensor. Must be one of the following

```
types: float32, float64, int32, complex64. 3-D or higher with shape [..., r x, c x].
```

- y: A Tensor. Must have the same type as x. 3-D or higher with shape [..., r y, c y].
- adj_x: An optional bool. Defaults to False. If True, adjoint the slices of x. Defaults to False.
- adj_y: An optional bool. Defaults to False. If True, adjoint the slices
 of y. Defaults to False.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as x. 3-D or higher with shape [..., r o, c o]

tf.matrix_determinant(input, name=None)

Calculates the determinant of a square matrix.

Args:

- input: A Tensor. Must be one of the following
 types: float32, float64. A tensor of shape [M, M].
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input. A scalar, equal to the determinant of the input.

```
tf.batch matrix determinant(input, name=None)
```

Calculates the determinants for a batch of square matrices.

The input is a tensor of shape [..., M, M] whose inner-most 2 dimensions form square matrices. The output is a 1-D tensor containing the determinants for all input submatrices [..., :, :].

• input: A Tensor. Must be one of the following

types: float32, float64. Shape is [..., M, M].

name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input. Shape is [...].

```
tf.matrix inverse(input, name=None)
```

Calculates the inverse of a square invertible matrix.

The op uses the Cholesky decomposition if the matrix is symmetric positive definite and LU decomposition with partial pivoting otherwise.

If the matrix is not invertible there is no guarantee what the op does. It may detect the condition and raise an exception or it may simply return a garbage result.

Args:

• input: A Tensor. Must be one of the following

types: float32, float64. Shape is [M, M].

name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input. Shape is [M, M] containing the matrix inverse of the input.

```
tf.batch matrix inverse(input, name=None)
```

Calculates the inverse of square invertible matrices.

The input is a tensor of shape [..., M, M] whose inner-most 2 dimensions form square matrices. The output is a tensor of the same shape as the input containing the inverse for all input submatrices [..., :, :].

The op uses the Cholesky decomposition if the matrices are symmetric positive definite and LU decomposition with partial pivoting otherwise.

If a matrix is not invertible there is no guarantee what the op does. It may detect the condition and raise an exception or it may simply return a garbage result.

Args:

input: A Tensor. Must be one of the following

```
types: float32, float64. Shape is [..., M, M].
```

name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input. Shape is [..., M, M].

```
tf.cholesky(input, name=None)
```

Calculates the Cholesky decomposition of a square matrix.

The input has to be symmetric and positive definite. Only the lower-triangular part of the input will be used for this operation. The upper-triangular part will not be read.

The result is the lower-triangular matrix of the Cholesky decomposition of the input.

Args:

input: A Tensor. Must be one of the following

```
types: float64, float32. Shape is [M, M].
```

name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input. Shape is [M, M].

```
tf.batch cholesky(input, name=None)
```

Calculates the Cholesky decomposition of a batch of square matrices.

The input is a tensor of shape [..., M, M] whose inner-most 2 dimensions form square matrices, with the same constraints as the single matrix Cholesky decomposition above. The output is a tensor of the same shape as the input containing the Cholesky decompositions for all input submatrices [..., :, :].

• input: A Tensor. Must be one of the following

types: float64, float32. Shape is [..., M, M].

name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input. Shape is [..., M, M].

```
tf.self adjoint eig(input, name=None)
```

Calculates the Eigen Decomposition of a square Self-Adjoint matrix.

Only the lower-triangular part of the input will be used in this case. The upper-triangular part will not be read.

The result is a M+1 x M matrix whose first row is the eigenvalues, and subsequent rows are eigenvectors.

Args:

input: A Tensor. Must be one of the following

types: float64, float32. Shape is [M, M].

name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input. Shape is [M+1, M].

```
tf.batch self adjoint eig(input, name=None)
```

Calculates the Eigen Decomposition of a batch of square self-adjoint matrices.

The input is a tensor of shape [..., M, M] whose inner-most 2 dimensions form square matrices, with the same constraints as the single matrix SelfAdjointEig.

The result is a '[..., M+1, M] matrix with [..., 0,:] containing the eigenvalues, and subsequent [...,1:,:] containing the eigenvectors.

Args:

input: A Tensor. Must be one of the following

types: float64, float32. Shape is [..., M, M].

name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input. Shape is [..., M+1, M].

```
tf.matrix solve(matrix, rhs, name=None)
```

Solves a system of linear equations. Checks for invertibility.

Args:

matrix: A Tensor. Must be one of the following

```
types: float32, float64. Shape is [M, M].
```

- rhs: A Tensor. Must have the same type as matrix. Shape is [M,
 K].
- name: A name for the operation (optional).

A Tensor. Has the same type as matrix. Shape is [M, K] containing the tensor that solves matrix * output = rhs.

```
tf.batch matrix solve(matrix, rhs, name=None)
```

Solves systems of linear equations. Checks for invertibility.

Matrix is a tensor of shape [..., M, M] whose inner-most 2 dimensions form square matrices. Rhs is a tensor of shape [..., M, K]. The output is a tensor shape [..., M, K] where each output matrix satisfies matrix[..., :, :] output[..., :, :] = rhs[..., :, :].

- matrix: A Tensor. Must be one of the following
 types: float32, float64. Shape is [..., M, M].
- rhs: A Tensor. Must have the same type as matrix. Shape is [...,
 M, K].
- name: A name for the operation (optional).

A Tensor. Has the same type as matrix. Shape is [..., M, K].

```
tf.matrix_triangular_solve(matrix, rhs, lower=None,
name=None)
```

Solves a system of linear equations with an upper or lower triangular matrix by

backsubstitution.

matrix is a matrix of shape [M, M]. If lower is True then the strictly upper triangular part of matrix is ignored. If lower is False then the strictly lower triangular part of matrix is ignored. rhs is a matrix of shape [M, K]`.

The output is a matrix of shape [M, K]. If lower is True then the output satisfies $\sum_{ik=0} \sum_{k=0} k=0$ imatrix[i, k] * output[k, j] = rhs[i, j]. If lower is false then output satisfies $\sum_{k=1} k=i \sum_{k=i} k=i k-1$ matrix[i, k] * output[k, j] = rhs[i, j].

- matrix: A Tensor. Must be one of the following
 types: float32, float64. Shape is [M, M].
- rhs: A Tensor. Must have the same type as matrix. Shape is [M,
 K].

- lower: An optional bool. Defaults to True. Boolean indicating whether matrix is lower or upper triangular.
- name: A name for the operation (optional).

A Tensor. Has the same type as matrix. Shape is [M, K].

tf.batch_matrix_triangular_solve(matrix, rhs, lower=None,
name=None)

Solves systems of linear equations with upper or lower triangular matrices by

backsubstitution.

matrix is a tensor of shape [..., M, M] whose inner-most 2 dimensions form square matrices. If lower istrue then the strictly upper triangular part of each inner-most matrix is ignored. If lower is False then the strictly lower triangular part of each inner-most matrix is ignored. rhs is a tensor of shape [..., M, K]`.

The output is a tensor of shape [..., M, K]. If lower is True then the output satisfies $\sum_{ik=0}\sum_{k=0}$ matrix[..., i, k] * output[..., k, j] = rhs[..., i, j]. If lower is false then the strictly then the output satisfies $sum_{K-1k=i}sum_{K-1k=i}sum_{K-1}i$, i, k] * output[..., k, j] = rhs[..., i, j].

- matrix: A Tensor. Must be one of the following
 types: float32, float64. Shape is [..., M, M].
- rhs: A Tensor. Must have the same type as matrix. Shape is [...,
 M, K].
- lower: An optional bool. Defaults to True. Boolean indicating whether matrix is lower or upper triangular.
- name: A name for the operation (optional).

A Tensor. Has the same type as matrix. Shape is [..., M, K].

```
tf.matrix_solve_ls(matrix, rhs, 12_regularizer=0.0,
fast=True, name=None)
```

Solves a linear least-squares problem.

Below we will use the following notation $matrix=A \in R_m \times nA \in \Re m \times n$, $rhs=B \in R_m \times kB \in \Re m \times k$, output= $X \in R_n \times kX \in \Re n \times k$, 12_regularizer= $\lambda \lambda$.

 $R_{n \times k} ||AZ - B||_{2F} + \lambda ||Z||_{2F} X = argmin Z \in \Re n \times k ||AZ - B||_{F} 2 + \lambda ||Z||_{F} 2.$

If fast is True, then the solution is computed by solving the normal equations using Cholesky decomposition. Specifically, if $m\ge nm\ge n$ then $X=(ATA+\lambda I)-1ATBX=(ATA+\lambda I)-1ATB$, which solves the regularized least-squares problem X=argminz \in

If m<nm<n then output is computed

as $X=AT(AAT+\lambda I)-1BX=AT(AAT+\lambda I)-1B$, which (for $\lambda=0\lambda=0$) is the minimum-norm solution to the under-determined linear system, i.e. $X=argminZ\in Rn \times k||Z||2FX=argminZ\in \Re n \times k||Z||F2$, subject to AZ=BAZ=B. Notice that the fast path is only numerically stable when AA is numerically full rank and has a condition number $cond(A)<1\varepsilon mach \sqrt{cond(A)}<1\varepsilon mach$ or $\lambda\lambda$ is sufficiently large.

If fast is False then the solution is computed using the rank revealing QR decomposition with column pivoting. This will always compute a least-squares solution that minimizes the residual norm $\|AX-B\|_{2F}\|AX-B\|_{F2}$, even when AAis rank deficient or ill-conditioned. Notice: The current version does not compute a minimum norm solution. If fast is False then 12_regularizer is ignored.

Args:

- matrix: 2-D Tensor of shape [M, N].
- rhs: 2-D Tensor of shape is [M, K].
- 12 regularizer: **0-D** double Tensor. **Ignored if** fast=False.
- fast: bool. Defaults to True.
- name: string, optional name of the operation.

Returns:

output: Matrix of shape [N, K] containing the matrix that
 solves matrix * output = rhs in the least-squares sense.

```
tf.batch_matrix_solve_ls(matrix, rhs, 12_regularizer=0.0,
fast=True, name=None)
```

Solves multiple linear least-squares problems.

```
matrix is a tensor of shape [..., M, N] whose inner-most 2 dimensions form M-by-N matrices. Rhs is a tensor of shape [..., M, K] whose inner-most 2 dimensions form M-by-K matrices. The computed output is aTensor of shape [..., N, K] whose inner-most 2 dimensions form M-by-K matrices that solve the equationsmatrix[..., :, :] * output[..., :, :] = rhs[..., :, :] in the least squares sense.
```

Below we will use the following notation for each pair of matrix and right-hand sides in the batch:

matrix= $A \in R_m \times nA \in \Re m \times n$, rhs= $B \in R_m \times kB \in \Re m \times k$, output= $X \in R_n \times kX$ $\in \Re n \times k$, 12_regularizer= $\lambda \lambda$.

If fast is True, then the solution is computed by solving the normal equations using Cholesky decomposition. Specifically, if $m \ge nm \ge n$ then $X = (ATA + \lambda I) - 1ATBX = (ATA + \lambda I) - 1ATB$, which solves the least-squares problem $X = argminz \in R_n \times ||AZ - B||_{2F} + \lambda ||Z||_{2F} \times = argminZ \in \Re n \times k ||AZ - B||_{F} + \lambda ||Z||_{F} \times ||AZ - B||_{F} + \lambda ||Z||_{F} \times ||AZ - B||_{F} \times ||AZ - B||_{$

to AZ=BAZ=B. Notice that the fast path is only numerically stable when AA is numerically full rank and has a condition $number\ cond(A) < 1 \le mach \lor cond($

If fast is False then the solution is computed using the rank revealing QR decomposition with column pivoting. This will always compute a least-squares solution that minimizes the residual norm $||AX-B||_{2F}||AX-B||_{F2}$, even when AAis rank deficient or ill-conditioned. Notice: The current version does not compute a minimum norm solution. If fast is False then 12_regularizer is ignored.

Args:

- matrix: Tensor of shape [..., M, N].
- rhs: Tensor of shape [..., M, K].
- 12 regularizer: **0-D** double Tensor. **Ignored if** fast=False.
- fast: bool. Defaults to True.
- name: string, optional name of the operation.

Returns:

output: Tensor of shape [..., N, K] whose inner-most 2
dimensions form M-by-K matrices that solve the
equations matrix[..., :, :] * output[..., :, :] =
rhs[..., :, :] in the least squares sense.

Complex Number Functions

TensorFlow provides several operations that you can use to add complex number functions to your graph.

```
tf.complex(real, imag, name=None)
```

Converts two real numbers to a complex number.

Given a tensor real representing the real part of a complex number, and a tensor imag representing the imaginary part of a complex number, this operation computes complex numbers elementwise of the form a+bja+bj, where a represents the real part and b represents the imag part.

The input tensors real and imag must be the same shape.

For example:

```
# tensor 'real' is [2.25, 3.25]
# tensor `imag` is [4.75, 5.75]
tf.complex(real, imag) ==> [[2.25 + 4.74j], [3.25 + 5.75j]]
```

Args:

- real: A Tensor of type float.
- imag: A Tensor of type float.
- name: A name for the operation (optional).

Returns:

A Tensor of type complex64.

```
tf.complex abs(x, name=None)
```

Computes the complex absolute value of a tensor.

Given a tensor x of complex numbers, this operation returns a tensor of type float that is the absolute value of each element in x. All elements in x must be complex numbers of the form a+bja+bj. The absolute value is computed as $a2+b2------\sqrt{a2+b2}$.

For example:

```
# tensor 'x' is [[-2.25 + 4.75j], [-3.25 + 5.75j]]
tf.complex_abs(x) ==> [5.25594902, 6.60492229]
```

Args:

- x: A Tensor of type complex64.
- name: A name for the operation (optional).

Returns:

A Tensor of type float32.

```
tf.conj(in , name=None)
```

Returns the complex conjugate of a complex number.

Given a tensor in of complex numbers, this operation returns a tensor of complex numbers that are the complex conjugate of each element in in. The complex numbers in in must be of the form a+bja+bj, where a is the real part and b is the imaginary part. The complex conjugate returned by this operation is of the form a-bja-bj.

For example:

```
# tensor 'in' is [-2.25 + 4.75j, 3.25 + 5.75j]
tf.conj(in) ==> [-2.25 - 4.75j, 3.25 - 5.75j]
```

Args:

- in_: A Tensor of type complex64.
- name: A name for the operation (optional).

Returns:

A Tensor of type complex64.

```
tf.imag(in , name=None)
```

Returns the imaginary part of a complex number.

Given a tensor in of complex numbers, this operation returns a tensor of type float that is the imaginary part of each element in in.

All elements in in must be complex numbers of the form a+bja+bj, where a is the real part and bis the imaginary part returned by this operation.

For example:

```
# tensor 'in' is [-2.25 + 4.75j, 3.25 + 5.75j]
tf.imag(in) ==> [4.75, 5.75]
```

Args:

- in : A Tensor of type complex64.
- name: A name for the operation (optional).

Returns:

A Tensor of type float32.

```
tf.real(in , name=None)
```

Returns the real part of a complex number.

Given a tensor in of complex numbers, this operation returns a tensor of type float that is the real part of each element in in. All elements in in must be complex numbers of the form a+bja+bj, where a is the real part returned by this operation and b is the imaginary part.

For example:

```
# tensor 'in' is [-2.25 + 4.75j, 3.25 + 5.75j]
tf.real(in) ==> [-2.25, 3.25]
```

Args:

- in : A Tensor of type complex64.
- name: A name for the operation (optional).

Returns:

A Tensor of type float32.

```
tf.fft2d(in_, name=None)
```

Compute the 2-dimensional discrete Fourier Transform.

Args:

- in : A Tensor of type complex64. A complex64 matrix.
- name: A name for the operation (optional).

Returns:

A Tensor of type complex64. The 2D Fourier Transform of in.

```
tf.ifft2d(in_, name=None)
```

Compute the inverse 2-dimensional discrete Fourier Transform.

- in : A Tensor of type complex64. A complex64 matrix.
- name: A name for the operation (optional).

A Tensor of type complex64. The inverse 2D Fourier Transform of in.

Reduction

TensorFlow provides several operations that you can use to perform common math computations that reduce various dimensions of a tensor.

```
tf.reduce_sum(input_tensor, reduction_indices=None,
keep_dims=False, name=None)
```

Computes the sum of elements across dimensions of a tensor.

Reduces input_tensor along the dimensions given in reduction_indices. Unless keep_dims is true, the rank of the tensor is reduced by 1 for each entry in reduction_indices.

If $keep_dims$ is true, the reduced dimensions are retained with length 1.

If reduction_indices has no entries, all dimensions are reduced, and a tensor with a single element is returned.

For example:

```
# 'x' is [[1, 1, 1]
# [1, 1, 1]]
```

```
tf.reduce_sum(x) ==> 6
tf.reduce_sum(x, 0) ==> [2, 2, 2]
tf.reduce_sum(x, 1) ==> [3, 3]
tf.reduce_sum(x, 1, keep_dims=True) ==> [[3], [3]]
tf.reduce_sum(x, [0, 1]) ==> 6
```

Args:

- input tensor: The tensor to reduce. Should have numeric type.
- reduction_indices: The dimensions to reduce. If None (the default),
 reduces all dimensions.
- keep dims: If true, retains reduced dimensions with length 1.
- name: A name for the operation (optional).

Returns:

The reduced tensor.

```
tf.reduce_prod(input_tensor, reduction_indices=None,
keep dims=False, name=None)
```

Computes the product of elements across dimensions of a tensor.

Reduces input_tensor along the dimensions given in reduction_indices. Unless keep_dims is true, the rank of the tensor is reduced by 1 for each entry in reduction_indices.

If keep_dims is true, the reduced dimensions are retained with length 1.

If reduction_indices has no entries, all dimensions are reduced, and a tensor with a single element is returned.

Args:

- input_tensor: The tensor to reduce. Should have numeric type.
- reduction_indices: The dimensions to reduce. If None (the default),
 reduces all dimensions.
- keep dims: If true, retains reduced dimensions with length 1.
- name: A name for the operation (optional).

Returns:

The reduced tensor.

```
tf.reduce_min(input_tensor, reduction_indices=None,
keep dims=False, name=None)
```

Computes the minimum of elements across dimensions of a tensor.

Reduces input_tensor along the dimensions given in reduction_indices. Unless keep_dims is true, the rank of the tensor is reduced by 1 for each entry in reduction indices.

If $keep_dims$ is true, the reduced dimensions are retained with length 1.

If reduction_indices has no entries, all dimensions are reduced, and a tensor with a single element is returned.

Args:

• input_tensor: The tensor to reduce. Should have numeric type.

- reduction_indices: The dimensions to reduce. If None (the default), reduces all dimensions.
- keep dims: If true, retains reduced dimensions with length 1.
- name: A name for the operation (optional).

The reduced tensor.

```
tf.reduce_max(input_tensor, reduction_indices=None,
keep dims=False, name=None)
```

Computes the maximum of elements across dimensions of a tensor.

Reduces input_tensor along the dimensions given in reduction_indices. Unless keep_dims is true, the rank of the tensor is reduced by 1 for each entry in reduction_indices.

If keep_dims is true, the reduced dimensions are retained with length 1.

If reduction_indices has no entries, all dimensions are reduced, and a tensor with a single element is returned.

- input_tensor: The tensor to reduce. Should have numeric type.
- reduction_indices: The dimensions to reduce. If None (the default),
 reduces all dimensions.
- keep_dims: If true, retains reduced dimensions with length 1.

• name: A name for the operation (optional).

Returns:

The reduced tensor.

```
tf.reduce_mean(input_tensor, reduction_indices=None,
keep dims=False, name=None)
```

Computes the mean of elements across dimensions of a tensor.

Reduces input_tensor along the dimensions given in reduction_indices. Unless keep_dims is true, the rank of the tensor is reduced by 1 for each entry in reduction indices.

If keep_dims is true, the reduced dimensions are retained with length 1.

If reduction_indices has no entries, all dimensions are reduced, and a tensor with a single element is returned.

For example:

```
# 'x' is [[1., 1.]
# [2., 2.]]

tf.reduce_mean(x) ==> 1.5

tf.reduce_mean(x, 0) ==> [1.5, 1.5]

tf.reduce_mean(x, 1) ==> [1., 2.]
```

Args:

• input_tensor: The tensor to reduce. Should have numeric type.

- reduction_indices: The dimensions to reduce. If None (the default),
 reduces all dimensions.
- keep dims: If true, retains reduced dimensions with length 1.
- name: A name for the operation (optional).

The reduced tensor.

```
tf.reduce_all(input_tensor, reduction_indices=None,
keep dims=False, name=None)
```

Computes the "logical and" of elements across dimensions of a tensor.

Reduces input_tensor along the dimensions given in reduction_indices. Unless keep_dims is true, the rank of the tensor is reduced by 1 for each entry in reduction_indices.

If keep_dims is true, the reduced dimensions are retained with length 1.

If reduction_indices has no entries, all dimensions are reduced, and a tensor with a single element is returned.

For example:

Args:

- input_tensor: The boolean tensor to reduce.
- reduction_indices: The dimensions to reduce. If None (the default),
 reduces all dimensions.
- keep dims: If true, retains reduced dimensions with length 1.
- name: A name for the operation (optional).

Returns:

The reduced tensor.

```
tf.reduce_any(input_tensor, reduction_indices=None,
keep_dims=False, name=None)
```

Computes the "logical or" of elements across dimensions of a tensor.

Reduces input_tensor along the dimensions given in reduction_indices. Unless keep_dims is true, the rank of the tensor is reduced by 1 for each entry in reduction_indices.

If $keep_dims$ is true, the reduced dimensions are retained with length 1.

If reduction_indices has no entries, all dimensions are reduced, and a tensor with a single element is returned.

For example:

```
# 'x' is [[True, True]
# [False, False]]

tf.reduce_any(x) ==> True

tf.reduce_any(x, 0) ==> [True, True]
```

```
tf.reduce_any(x, 1) ==> [True, False]
```

Args:

- input tensor: The boolean tensor to reduce.
- reduction_indices: The dimensions to reduce. If None (the default),
 reduces all dimensions.
- keep_dims: If true, retains reduced dimensions with length 1.
- name: A name for the operation (optional).

Returns:

The reduced tensor.

```
tf.accumulate_n(inputs, shape=None, tensor_dtype=None,
name=None)
```

Returns the element-wise sum of a list of tensors.

Optionally, pass shape and tensor_dtype for shape and type checking, otherwise, these are inferred.

For example:

- inputs: A list of Tensor objects, each with same shape and type.
- shape: Shape of elements of inputs.
- tensor dtype: The type of inputs.
- name: A name for the operation (optional).

A Tensor of same shape and type as the elements of inputs.

Raises:

 ValueError: If inputs don't all have same shape and dtype or the shape cannot be inferred.

Segmentation

TensorFlow provides several operations that you can use to perform common math computations on tensor segments. Here a segmentation is a partitioning of a tensor along the first dimension, i.e. it defines a mapping from the first dimension onto segment ids.

The $segment_ids$ tensor should be the size of the first dimension, d0, with consecutive IDs in the range 0 to k, where k<d0. In particular, a segmentation of a matrix tensor is a mapping of rows to segments.

For example:

```
c = tf.constant([[1,2,3,4], [-1,-2,-3,-4], [5,6,7,8]])
tf.segment_sum(c, tf.constant([0, 0, 1]))
==> [[0 0 0 0]
        [5 6 7 8]]
```

```
tf.segment sum(data, segment ids, name=None)
```

Computes the sum along segments of a tensor.

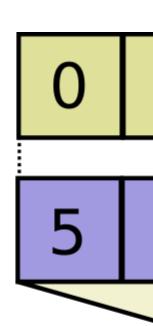

Read the section on Segmentation for an explanation of segments.

Computes a tensor such that outputi=∑jdatajoutputi=∑jdataj where sum

is over j such that segment ids[j] == i.

segment_ids

data

Args:

data: A Tensor. Must be one of the following

types: float32, float64, int32, int64, uint8, int16, int8, uint16.

segment_ids: A Tensor. Must be one of the following

types: int32, int64. A 1-D tensor whose rank is equal to the rank

of data's first dimension. Values should be sorted and can be repeated.

name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as data. Has same shape as data, except for dimension 0 which has size k, the number of segments.

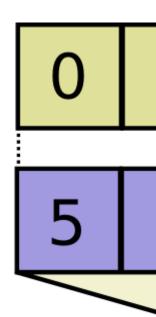

```
tf.segment prod(data, segment ids, name=None)
```

Computes the product along segments of a tensor.

Read <u>the section on Segmentation</u> for an explanation of segments. Computes a tensor such that $outputi=\prod_{j}data_{j}outputi=\prod_{j}data_{j}$ where the product is over j such that segment ids[j] == i.

segment_ids

data

Args:

- data: A Tensor. Must be one of the following
 types: float32, float64, int32, int64, uint8, int16, int8, uint16.
- segment_ids: A Tensor. Must be one of the following
 types: int32, int64. A 1-D tensor whose rank is equal to the rank
 of data's first dimension. Values should be sorted and can be repeated.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as data. Has same shape as data, except for dimension 0 which has size k, the number of segments.

```
tf.segment min(data, segment ids, name=None)
```

Computes the minimum along segments of a tensor.

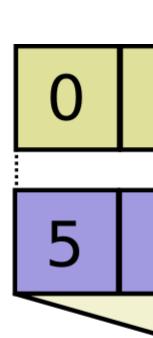

Read <u>the section on Segmentation</u> for an explanation of segments. Computes a tensor such

that outputi=minj(dataj)outputi=minj(dataj) where min is over j such

that segment ids[j] == i.

segment_ids

data

Args:

• data: A Tensor. Must be one of the following

types: float32, float64, int32, int64, uint8, int16, int8, uint16.

segment ids: A Tensor. Must be one of the following

types: int32, int64. A 1-D tensor whose rank is equal to the rank

of data's first dimension. Values should be sorted and can be repeated.

name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as data. Has same shape as data, except for dimension 0 which has size k, the number of segments.

```
tf.segment_max(data, segment_ids, name=None)
```

Computes the maximum along segments of a tensor.

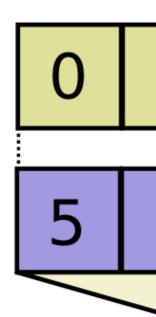

Read <u>the section on Segmentation</u> for an explanation of segments. Computes a tensor such

that $outputi=max_j(data_j)outputi=max_j(data_j)$ where max is over j such

that segment_ids[j] == i.

segment_ids

data

Args:

- data: A Tensor. Must be one of the following
 types: float32, float64, int32, int64, uint8, int16, int8, uint16.
- segment_ids: A Tensor. Must be one of the following
 types: int32, int64. A 1-D tensor whose rank is equal to the rank
 of data's first dimension. Values should be sorted and can be repeated.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as data. Has same shape as data, except for dimension 0 which has size k, the number of segments.

```
tf.segment mean(data, segment ids, name=None)
```

Computes the mean along segments of a tensor.

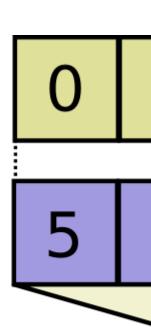

Read <u>the section on Segmentation</u> for an explanation of segments. Computes a tensor such

that outputi=∑jdatajNoutputi=∑jdatajN where mean is over j such

that segment_ids[j] == i andN is the total number of values summed.

segment_ids

data

Args:

data: A Tensor. Must be one of the following

types: float32, float64, int32, int64, uint8, int16, int8, uint16.

- segment_ids: A Tensor. Must be one of the following
 types: int32, int64. A 1-D tensor whose rank is equal to the rank
 of data's first dimension. Values should be sorted and can be repeated.
- name: A name for the operation (optional).

A Tensor. Has the same type as data. Has same shape as data, except for dimension 0 which has size k, the number of segments.

```
tf.unsorted_segment_sum(data, segment_ids, num_segments,
name=None)
```

Computes the sum along segments of a tensor.

Read <u>the section on Segmentation</u> for an explanation of segments. Computes a tensor such that $outputi=\sum_{j}data_{j}outputi=\sum_{j}data_{j}$ where sum is over j such that segment ids[j] == i.

Unlike SegmentSum, segment_ids need not be sorted and need not cover all values in the full range of valid values.

If the sum is empty for a given segment ID i, output[i] = 0.

num_segments should equal the number of distinct segment IDs.

segment_ids

0

data

5

Args:

- data: A Tensor. Must be one of the following
 types: float32, float64, int32, int64, uint8, int16,int8, uint16.
- segment_ids: A Tensor. Must be one of the following
 types: int32, int64. A 1-D tensor whose rank is equal to the rank
 of data's first dimension.
- num_segments: A Tensor of type int32.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as data. Has same shape as data, except for dimension 0 which has sizenum segments.

```
tf.sparse_segment_sum(data, indices, segment_ids,
name=None)
```

Computes the sum along sparse segments of a tensor.

Read the section on Segmentation for an explanation of segments. Like SegmentSum, but segment_ids can have rank less than data's first dimension, selecting a subset of dimension 0, specified by indices.

For example:

```
c = tf.constant([[1,2,3,4], [-1,-2,-3,-4], [5,6,7,8]])
# Select two rows, one segment.
tf.sparse segment sum(c, tf.constant([0, 1]), tf.constant([0,
0]))
 ==> [[0 0 0 0]]
# Select two rows, two segment.
tf.sparse segment sum(c, tf.constant([0, 1]), tf.constant([0,
1]))
 ==> [[ 1 2 3 4]
     [-1 -2 -3 -4]]
# Select all rows, two segments.
tf.sparse_segment_sum(c, tf.constant([0, 1, 2]), tf.constant([0,
0, 1]))
 ==> [[0 0 0 0]
      [5 6 7 8]]
# Which is equivalent to:
tf.segment sum(c, tf.constant([0, 0, 1]))
```

Args:

- data: A Tensor. Must be one of the following
 types: float32, float64, int32, int64, uint8, int16, int8, uint16.
- indices: A Tensor of type int32. A 1-D tensor. Has same rank as segment ids.
- segment_ids: A Tensor of type int32. A 1-D tensor. Values should be sorted and can be repeated.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as data. Has same shape as data, except for dimension 0 which has size k, the number of segments.

```
tf.sparse_segment_mean(data, indices, segment_ids,
name=None)
```

Computes the mean along sparse segments of a tensor.

Read the section on Segmentation for an explanation of segments.

Like SegmentMean, but segment_ids can have rank less than data's first dimension, selecting a subset of dimension 0, specified by indices.

data: A Tensor. Must be one of the following
 types: float32, float64.

- indices: A Tensor of type int32. A 1-D tensor. Has same rank
 as segment_ids.
- segment_ids: A Tensor of type int32. A 1-D tensor. Values should be sorted and can be repeated.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as data. Has same shape as data, except for dimension 0 which has size k, the number of segments.

```
tf.sparse_segment_sqrt_n(data, indices, segment_ids,
name=None)
```

Computes the sum along sparse segments of a tensor divided by the sqrt of N.

N is the size of the segment being reduced.

Read the section on Segmentation for an explanation of segments.

Args:

• data: A Tensor. Must be one of the following

types: float32, float64.

- indices: A Tensor of type int32. A 1-D tensor. Has same rank
 as segment_ids.
- segment_ids: A Tensor of type int32. A 1-D tensor. Values should be sorted and can be repeated.
- name: A name for the operation (optional).

A Tensor. Has the same type as data. Has same shape as data, except for dimension 0 which has size k, the number of segments.

Sequence Comparison and Indexing

TensorFlow provides several operations that you can use to add sequence comparison and index extraction to your graph. You can use these operations to determine sequence differences and determine the indexes of specific values in a tensor.

```
tf.argmin(input, dimension, name=None)
```

Returns the index with the smallest value across dimensions of a tensor.

Args:

input: A Tensor. Must be one of the following

```
types: float32, float64, int64, int32, uint8, uint16, int16, int8,
complex64, qint8, quint8, qint32.
```

- dimension: A Tensor of type int32. int32, 0 <= dimension
 rank(input). Describes which dimension of the input Tensor to reduce across. For vectors, use dimension = 0.
- name: A name for the operation (optional).

A Tensor of type int64.

tf.argmax(input, dimension, name=None)

Returns the index with the largest value across dimensions of a tensor.

Args:

input: A Tensor. Must be one of the following

types: float32, float64, int64, int32, uint8, uint16, int16, int8,
complex64, qint8, quint8, qint32.

- dimension: A Tensor of type int32. int32, 0 <= dimension <
 rank(input). Describes which dimension of the input Tensor to reduce across. For vectors, use dimension = 0.
- name: A name for the operation (optional).

Returns:

A Tensor of type int64.

```
tf.listdiff(x, y, name=None)
```

Computes the difference between two lists of numbers or strings.

Given a list x and a list y, this operation returns a list out that represents all values that are in x but not in y. The returned list out is sorted in the same order that the numbers appear in x (duplicates are preserved). This operation also returns a list idx that represents the position of each out element in x. In other words:

```
out[i] = x[idx[i]] for i in [0, 1, ..., len(out) - 1]
```

For example, given this input:

```
x = [1, 2, 3, 4, 5, 6]

y = [1, 3, 5]
```

This operation would return:

```
out ==> [2, 4, 6]
idx ==> [1, 3, 5]
```

Args:

- x: A Tensor. 1-D. Values to keep.
- y: A Tensor. Must have the same type as x. 1-D. Values to remove.
- name: A name for the operation (optional).

Returns:

A tuple of Tensor objects (out, idx).

- out: A Tensor. Has the same type as x. 1-D. Values present in x but
 not in y.
- idx: A Tensor of type int32. 1-D. Positions of x values preserved
 in out.

```
tf.where(input, name=None)
```

Returns locations of true values in a boolean tensor.

This operation returns the coordinates of true elements in input. The coordinates are returned in a 2-D tensor where the first dimension (rows) represents the number of true elements, and the second dimension (columns) represents the coordinates of the true elements. Keep in mind, the shape of the output tensor can vary depending on how many true values there are in input. Indices are output in rowmajor order.

For example:

```
# 'input' tensor is [[True, False]
                  [True, False]]
# 'input' has two true values, so output has two coordinates.
# 'input' has rank of 2, so coordinates have two indices.
where (input) \Longrightarrow [[0, 0],
               [1, 0]]
# `input` tensor is [[[True, False]
#
                   [True, False]]
#
                   [[False, True]
#
                   [False, True]]
#
                   [[False, False]
                   [False, True]]]
# 'input' has 5 true values, so output has 5 coordinates.
# 'input' has rank of 3, so coordinates have three indices.
where (input) ==> [[0, 0, 0],
```

```
[0, 1, 0],
[1, 0, 1],
[1, 1, 1],
[2, 1, 1]]
```

Args:

- input: A Tensor of type bool.
- name: A name for the operation (optional).

Returns:

A Tensor of type int 64.

```
tf.unique(x, name=None)
```

Finds unique elements in a 1-D tensor.

This operation returns a tensor y containing all of the unique elements of x sorted in the same order that they occur in x. This operation also returns a tensor idx the same size as x that contains the index of each value of x in the unique output y. In other words:

```
y[idx[i]] = x[i] for i in [0, 1,...,rank(x) - 1]
```

For example:

```
# tensor 'x' is [1, 1, 2, 4, 4, 4, 7, 8, 8]
y, idx = unique(x)
y ==> [1, 2, 4, 7, 8]
idx ==> [0, 0, 1, 2, 2, 2, 3, 4, 4]
```

Args:

- x: A Tensor. 1-D.
- name: A name for the operation (optional).

Returns:

A tuple of Tensor objects (y, idx).

- y: A Tensor. Has the same type as x. 1-D.
- idx: A Tensor of type int32. 1-D.

```
tf.edit_distance(hypothesis, truth, normalize=True,
name='edit_distance')
```

Computes the Levenshtein distance between sequences.

This operation takes variable-length sequences (hypothesis and truth), each provided as a SparseTensor, and computes the Levenshtein distance. You can normalize the edit distance by length of truth by settingnormalize to true.

For example, given the following input:

```
# 'hypothesis' is a tensor of shape `[2, 1]` with variable-length
values:
# (0,0) = ["a"]
# (1,0) = ["b"]
hypothesis = tf.SparseTensor(
    [[0, 0, 0],
    [1, 0, 0]],
    ["a", "b"]
    (2, 1, 1))
```

```
# 'truth' is a tensor of shape `[2, 2]` with variable-length
values:
# (0,0) = []
# (0,1) = ["a"]
# (1,0) = ["b", "c"]
# (1,1) = ["a"]
truth = tf.SparseTensor(
    [[0, 1, 0],
        [1, 0, 0],
        [1, 1, 0]]
    ["a", "b", "c", "a"],
    (2, 2, 2))
normalize = True
```

This operation would return the following:

Args:

- hypothesis: A SparseTensor containing hypothesis sequences.
- truth: A SparseTensor containing truth sequences.
- normalize: A bool. If True, normalizes the Levenshtein distance by length of truth.
- name: A name for the operation (optional).

Returns:

A dense Tensor with rank R - 1, where R is the rank of the SparseTensor inputs hypothesis and truth.

Raises:

• TypeError: If either hypothesis or truth are not a SparseTensor.

```
tf.invert permutation(x, name=None)
```

Computes the inverse permutation of a tensor.

This operation computes the inverse of an index permutation. It takes a 1-D integer tensor x, which represents the indices of a zero-based array, and swaps each value with its index position. In other words, for an output tensor y and an input tensor x, this operation computes the following:

```
y[x[i]] = i \text{ for } i \text{ in } [0, 1, ..., len(x) - 1]
```

The values must include 0. There can be no duplicate values or negative values.

For example:

```
# tensor `x` is [3, 4, 0, 2, 1]
invert_permutation(x) ==> [2, 4, 3, 0, 1]
```

Args:

- x: A Tensor of type int32. 1-D.
- name: A name for the operation (optional).

Returns:

A Tensor of type int32. 1-D.

Other Functions and Classes

```
tf.scalar mul(scalar, x)
```

Multiplies a scalar times a Tensor or IndexedSlices object.

Intended for use in gradient code which might deal
with IndexedSlices objects, which are easy to multiply by a scalar
but more expensive to multiply with arbitrary tensors.

Args:

- scalar: A 0-D scalar Tensor. Must have known shape.
- x: A Tensor or IndexedSlices to be scaled.

Returns:

```
scalar * x of the same type (Tensor or IndexedSlices) as x.
```

Raises:

ValueError: if scalar is not a 0-D scalar.

```
tf.sparse_segment_sqrt_n_grad(grad, indices, segment_ids,
output dim0, name=None)
```

Computes gradients for SparseSegmentSqrtN.

Returns tensor "output" with same shape as grad, except for dimension 0 whose value is output_dim0.

Args:

• grad: A Tensor. Must be one of the following

types: float32, float64. gradient propagated to the SparseSegmentSqrtN op.

- indices: A Tensor of type int32. indices passed to the corresponding SparseSegmentSqrtN op.
- segment_ids: A Tensor of type int32. segment_ids passed to the corresponding SparseSegmentSqrtN op.
- output_dim0: A Tensor of type int32. dimension 0 of "data" passed to SparseSegmentSqrtN op.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as grad.

Control Flow Operations

TensorFlow provides several operations and classes that you can use to control the execution of operations and add conditional dependencies to your graph.

```
tf.identity(input, name=None)
```

Return a tensor with the same shape and contents as the input tensor or value. Args:

input: A Tensor.

name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input.

tf.tuple(tensors, name=None, control inputs=None)

Group tensors together.

This creates a tuple of tensors with the same values as the tensors argument, except that the value of each tensor is only returned after the values of all tensors have been computed. control_inputs contains additional ops that have to finish before this op finishes, but whose outputs are not returned. This can be used as a "join" mechanism for parallel computations: all the argument tensors can be computed in parallel, but the values of any tensor returned by tuple are only available after all the parallel computations are done.

See also group and with dependencies.

- tensors: A list of Tensors or IndexedSlices, some entries can
 be None.
- name: (optional) A name to use as a name scope for the operation.

• control inputs: List of additional ops to finish before returning. Returns: Same as tensors. Raises: • ValueError: If tensors does not contain any Tensor of IndexedSlices. • TypeError: If control inputs is not a list of Operation or Tensor objects. tf.group(*inputs, **kwargs) Create an op that groups multiple operations. When this op finishes, all ops in input have finished. This op has no output. See also tuple and with dependencies. Args: *inputs: One or more tensors to group. • **kwargs: Optional parameters to pass when constructing the NodeDef. • name: A name for this operation (optional).

	Returns:
	An Operation that executes all its inputs.
	Raises:
	ValueError: If an unknown keyword argument is provided, or if there are no inputs.
	tf.no_op(name=None)
	Does nothing. Only useful as a placeholder for control edges.
	Args:
•	name: A name for the operation (optional).
	Returns:
	The created Operation.
	tf.count_up_to(ref, limit, name=None)
	Increments 'ref' until it reaches 'limit'.
	This operation outputs "ref" after the update is done. This makes it easier to chain operations that need to use the updated value.

- ref: A mutable Tensor. Must be one of the following
 types: int32, int64. Should be from a scalarvariable node.
- limit: An int. If incrementing ref would bring it above limit, instead generates an 'OutOfRange' error.
- name: A name for the operation (optional).

A Tensor. Has the same type as ref. A copy of the input before increment. If nothing else modifies the input, the values produced will all be distinct.

tf.cond(pred, fn1, fn2, name=None)

Return either fn1() or fn2() based on the boolean predicate pred.

fn1 and fn2 both return lists of output tensors. fn1 and fn2 must have the same non-zero number and type of outputs.

Args:

- pred: A scalar determining whether to return the result of fn1 or fn2.
- fn1: The function to be performed if pred is true.
- fn2: The function to be performed if pref is false.
- name: Optional name prefix for the returned tensors.

Returns:

Tensors returned by the call to either fn1 or fn2. If the functions return a singleton list, the element is extracted from the list.

Raises:

- TypeError: if fn1 or fn2 is not callable.
- ValueError: if fn1 and fn2 do not return the same number of tensors, or return tensors of different types.
- Example:

```
x = tf.constant(2)
y = tf.constant(5)
def f1(): return tf.mul(x, 17)
def f2(): return tf.add(y, 23)
r = cond(math_ops.less(x, y), f1, f2)
# r is set to f1().
# Operations in f2 (e.g., tf.add) are not executed.
```

Logical Operators

TensorFlow provides several operations that you can use to add logical operators to your graph.

```
tf.logical and(x, y, name=None)
```

Returns the truth value of x AND y element-wise.

- x: A Tensor of type bool.
- y: A Tensor of type bool.

•	name: A name for the operation (optional).
	Returns:
	A Tensor of type bool.
	tf.logical_not(x, name=None)
	Returns the truth value of NOT x element-wise.
	Args:
•	x: A Tensor of type bool.
•	name: A name for the operation (optional).
	Returns:
	A Tensor of type bool.
	tf.logical_or(x, y, name=None)
	Returns the truth value of x OR y element-wise.
	Args:
•	x: A Tensor of type bool.
•	y: A Tensor of type bool.

• name: A name for the operation (optional).

Returns:

A Tensor of type bool.

```
tf.logical_xor(x, y, name='LogicalXor')
x \wedge y = (x \mid y) \& \sim (x \& y).
```

Comparison Operators

TensorFlow provides several operations that you can use to add comparison operators to your graph.

```
tf.equal(x, y, name=None)
```

Returns the truth value of (x == y) element-wise.

Args:

• x: A Tensor. Must be one of the following

types: float32, float64, uint8, int8, int16, int32, int64, complex
64, quint8, qint8, qint32, string.

- y: A Tensor. Must have the same type as x.
- name: A name for the operation (optional).

A Tensor of type bool.

```
tf.not equal(x, y, name=None)
```

Returns the truth value of (x != y) element-wise.

Args:

• x: A Tensor. Must be one of the following

types: float32, float64, uint8, int8, int16, int32, int64, complex
64, quint8, qint8, qint32, string.

- y: A Tensor. Must have the same type as \mathbf{x} .
- name: A name for the operation (optional).

Returns:

A Tensor of type bool.

```
tf.less(x, y, name=None)
```

Returns the truth value of (x < y) element-wise.

x: A Tensor. Must be one of the following types: float32, float64, int32, int64, uint8, int16, int8, uint16. • y: A Tensor. Must have the same type as x. • name: A name for the operation (optional). Returns: A Tensor of type bool. tf.less equal(x, y, name=None) Returns the truth value of $(x \le y)$ element-wise. Args: x: A Tensor. Must be one of the following types: float32, float64, int32, int64, uint8, int16, int8, uint16. y: A Tensor. Must have the same type as x. name: A name for the operation (optional). Returns: A Tensor of type bool.

```
tf.greater(x, y, name=None)
```

Returns the truth value of (x > y) element-wise.

Args:

• x: A Tensor. Must be one of the following

types: float32, float64, int32, int64, uint8, int16, int8, uint16.

- y: A Tensor. Must have the same type as x.
- name: A name for the operation (optional).

Returns:

A Tensor of type bool.

```
tf.greater equal(x, y, name=None)
```

Returns the truth value of $(x \ge y)$ element-wise.

Args:

• x: A Tensor. Must be one of the following

types: float32, float64, int32, int64, uint8, int16, int8, uint16.

- y: A Tensor. Must have the same type as x.
- name: A name for the operation (optional).

Returns:

```
tf.select(condition, t, e, name=None)
```

Selects elements from t or e, depending on condition.

The t, and e tensors must all have the same shape, and the output will also have that shape. The <code>condition</code>tensor must be a scalar if t and e are scalars. If t and e are vectors or higher rank, then <code>condition</code> must be either a vector with size matching the first dimension of t, or must have the same shape as t.

The condition tensor acts as a mask that chooses, based on the value at each element, whether the corresponding element / row in the output should be taken from t (if true) or e (if false).

If condition is a vector and t and e are higher rank matrices, then it chooses which row (outer dimension) to copy from t and e.

If condition has the same shape as t and e, then it chooses which element to copy from tand e.

For example:

Args:

- condition: A Tensor of type bool.
- t: A Tensor which may have the same shape as condition.
 If condition is rank 1, t may have higher rank, but its first dimension must match the size of condition.
- e: A Tensor with the same type and shape as t.
- name: A name for the operation (optional).

Returns:

A Tensor with the same type and shape as t and e.

```
tf.where(input, name=None)
```

Returns locations of true values in a boolean tensor.

This operation returns the coordinates of true elements in input. The coordinates are returned in a 2-D tensor where the first dimension (rows) represents the number of true elements, and the second dimension (columns) represents the coordinates of the true elements.

Keep in mind, the shape of the output tensor can vary depending on how many true values there are in input. Indices are output in row-major order.

For example:

```
# 'input' tensor is [[True, False]
                  [True, False]]
# 'input' has two true values, so output has two coordinates.
# 'input' has rank of 2, so coordinates have two indices.
where (input) \Longrightarrow [[0, 0],
                [1, 0]]
# `input` tensor is [[[True, False]
                   [True, False]]
#
                  [[False, True]
#
                   [False, True]]
#
                   [[False, False]
                   [False, True]]]
# 'input' has 5 true values, so output has 5 coordinates.
# 'input' has rank of 3, so coordinates have three indices.
where (input) ==> [[0, 0, 0],
               [0, 1, 0],
               [1, 0, 1],
               [1, 1, 1],
                [2, 1, 1]]
```

Args:

- input: A Tensor of type bool.
- name: A name for the operation (optional).

Returns:

A Tensor of type int64.

Debugging Operations

```
tf.is finite(x, name=None)
```

Returns which elements of x are finite.

Args:

- x: A Tensor. Must be one of the following types: float32, float64.
- name: A name for the operation (optional).

Returns:

A Tensor of type bool.

```
tf.is inf(x, name=None)
```

Returns which elements of x are Inf.

Args:

- x: A Tensor. Must be one of the following types: float32, float64.
- name: A name for the operation (optional).

Returns:

A Tensor of type bool.

```
tf.is nan(x, name=None)
   Returns which elements of x are NaN.
   Args:
  x: A Tensor. Must be one of the following types: float32, float64.
 name: A name for the operation (optional).
   Returns:
  A Tensor of type bool.
  tf.verify_tensor_all_finite(t, msg, name=None)
  Assert that the tensor does not contain any NaN's or Inf's.
   Args:
  t: Tensor to check.
• msg: Message to log on failure.
  name: A name for this operation (optional).
   Returns:
   Same tensor as t.
```

tf.check numerics(tensor, message, name=None)

Checks a tensor for NaN and Inf values.

When run, reports an InvalidArgument error if tensor has any values that are not a number (NaN) or infinity (Inf). Otherwise, passes tensor as-is.

Args:

tensor: A Tensor. Must be one of the following

types: float32, float64.

- message: A string. Prefix of the error message.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as tensor.

tf.add_check_numerics_ops()

Connect a check_numerics to every floating point tensor.

 ${\tt check_numerics} \ \textbf{operations} \ \textbf{themselves} \ \textbf{are} \ \textbf{added} \ \textbf{for}$

each float or double tensor in the graph. For all ops in the graph,

the check_numerics op for all of its (float or double) inputs is

guaranteed to run before the check_numerics op on any of its outputs.

Returns:

A group op depending on all check numerics ops added.

tf.Assert(condition, data, summarize=None, name=None)

Asserts that the given condition is true.

If condition evaluates to false, print the list of tensors in data. summarize determines how many entries of the tensors to print.

Args:

- condition: The condition to evaluate.
- data: The tensors to print out when condition is false.
- summarize: Print this many entries of each tensor.
- name: A name for this operation (optional).

tf.Print(input_, data, message=None, first_n=None,
summarize=None, name=None)

Prints a list of tensors.

This is an identity op with the side effect of printing data when evaluating.

Args:

- input: A tensor passed through this op.
- data: A list of tensors to print out when op is evaluated.
- message: A string, prefix of the error message.
- first_n: Only log first_n number of times. Negative numbers log always; this is the default.
- summarize: Only print this many entries of each tensor. If None, then
 a maximum of 3 elements are printed per input tensor.
- name: A name for the operation (optional).

Returns:

Same tensor as input .

Images

- Other Functions and Classes
- tf.image.saturate cast(image, dtype)

Encoding and Decoding

TensorFlow provides Ops to decode and encode JPEG and PNG formats. Encoded images are represented by scalar string Tensors, decoded images by 3-D uint8 tensors of shape [height, width,

channels]. (PNG also supports uint16.)

The encode and decode Ops apply to one image at a time. Their input and output are all of variable size. If you need fixed size images, pass the output of the decode Ops to one of the cropping and resizing Ops.

Note: The PNG encode and decode Ops support RGBA, but the conversions Ops presently only support RGB, HSV, and GrayScale. Presently, the alpha channel has to be stripped from the image and re-attached using slicing ops.

tf.image.decode_jpeg(contents, channels=None, ratio=None,
fancy_upscaling=None, try_recover_truncated=None,
acceptable fraction=None, name=None)

Decode a JPEG-encoded image to a uint8 tensor.

The attr channels indicates the desired number of color channels for the decoded image.

Accepted values are:

- 0: Use the number of channels in the JPEG-encoded image.
- 1: output a grayscale image.
- 3: output an RGB image.

If needed, the JPEG-encoded image is transformed to match the requested number of color channels.

The attr ratio allows downscaling the image by an integer factor during decoding. Allowed values are: 1, 2, 4, and 8. This is much faster than downscaling the image later.

- contents: A Tensor of type string. 0-D. The JPEG-encoded image.
- channels: An optional int. Defaults to 0. Number of color channels for the decoded image.
- ratio: An optional int. Defaults to 1. Downscaling ratio.
- fancy_upscaling: An optional bool. Defaults to True. If true use a slower but nicer upscaling of the chroma planes (yuv420/422 only).
- try_recover_truncated: An optional bool. Defaults to False. If true try to recover an image from truncated input.

- acceptable_fraction: An optional float. Defaults to 1. The minimum required fraction of lines before a truncated input is accepted.
- name: A name for the operation (optional).

A Tensor of type uint8. 3-D with shape [height, width, channels]..

tf.image.encode_jpeg(image, format=None, quality=None,
progressive=None, optimize_size=None,
chroma_downsampling=None, density_unit=None,
x_density=None, y_density=None, xmp_metadata=None,
name=None)

JPEG-encode an image.

image is a 3-D uint8 Tensor of shape [height, width, channels].

The attr format can be used to override the color format of the encoded output. Values can be:

- '': Use a default format based on the number of channels in the image.
- grayscale: Output a grayscale JPEG image.

The channels dimension of image must be 1.

rgb: Output an RGB JPEG image. The channels dimension
 of image must be 3.

If format is not specified or is the empty string, a default format is picked in function of the number of channels inimage:

- 1: Output a grayscale image.
- 3: Output an RGB image.

- image: A Tensor of type uint8. 3-D with shape [height, width, channels].
- format: An optional string from: "", "grayscale", "rgb".
 Defaults to "". Per pixel image format.
- quality: An optional int. Defaults to 95. Quality of the compression from 0 to 100 (higher is better and slower).
- progressive: An optional bool. Defaults to False. If True, create a
 JPEG that loads progressively (coarse to fine).
- optimize_size: An optional bool. Defaults to False. If True, spend
 CPU/RAM to reduce size with no quality change.
- chroma_downsampling: An optional bool. Defaults to True.
 Seehttp://en.wikipedia.org/wiki/Chroma_subsampling.
- density_unit: An optional string from: "in", "cm". Defaults
 to "in". Unit used to specifyx_density and y_density: pixels per
 inch ('in') or centimeter ('cm').
- x_density: An optional int. Defaults to 300. Horizontal pixels per density unit.
- y_density: An optional int. Defaults to 300. Vertical pixels per density unit.

- xmp_metadata: An optional string. Defaults to "". If not empty,
 embed this XMP metadata in the image header.
- name: A name for the operation (optional).

A Tensor of type string. 0-D. JPEG-encoded image.

tf.image.decode_png(contents, channels=None, dtype=None,
name=None)

Decode a PNG-encoded image to a uint8 or uint16 tensor.

The attr channels indicates the desired number of color channels for the decoded image.

Accepted values are:

- 0: Use the number of channels in the PNG-encoded image.
- 1: output a grayscale image.
- 3: output an RGB image.
- 4: output an RGBA image.

If needed, the PNG-encoded image is transformed to match the requested number of color channels.

Args:

• contents: A Tensor of type string. 0-D. The PNG-encoded image.

- channels: An optional int. Defaults to 0. Number of color channels for the decoded image.
- dtype: An optional tf.DType from: tf.uint8, tf.uint16. Defaults to tf.uint8.
- name: A name for the operation (optional).

A Tensor of type dtype. 3-D with shape [height, width, channels].

tf.image.encode png(image, compression=None, name=None)

PNG-encode an image.

image is a 3-D uint8 or uint16 Tensor of shape [height, width,
channels] where channels is:

- 1: for grayscale.
- 3: for RGB.
- 4: for RGBA.

The ZLIB compression level, compression, can be -1 for the PNG-encoder default or a value from 0 to 9. 9 is the highest compression level, generating the smallest output, but is slower.

- image: A Tensor. Must be one of the following types: uint8, uint16.
 3-D with shape [height, width, channels].
- compression: An optional int. Defaults to -1. Compression level.
- name: A name for the operation (optional).

A Tensor of type string. 0-D. PNG-encoded image.

Resizing

The resizing Ops accept input images as tensors of several types. They always output resized images as float32 tensors.

The convenience function resize_images() supports both 4-D and 3-D tensors as input and output. 4-D tensors are for batches of images, 3-D tensors for individual images.
Other resizing Ops only support 4-D batches of images as

```
input: resize_area, resize_bicubic,resize_bilinear, resize_nea
rest neighbor.
```

Example:

```
# Decode a JPG image and resize it to 299 by 299 using default
method.
image = tf.image.decode_jpeg(...)
resized_image = tf.image.resize_images(image, 299, 299)
```

```
tf.image.resize_images(images, new_height, new_width,
method=0, align corners=False)
```

Resize images to new_width, new_height using the specified method.

Resized images will be distorted if their original aspect ratio is not the same as new width, new height. To avoid distortions

```
See resize_image_with_crop_or_pad.
```

method can be one of:

- ResizeMethod.BILINEAR: Bilinear interpolation.
- ResizeMethod.NEAREST NEIGHBOR: Nearest neighbor interpolation.
- ResizeMethod.BICUBIC: Bicubic interpolation.
- ResizeMethod.AREA: Area interpolation.

Args:

- images: 4-D Tensor of shape [batch, height, width, channels] or 3-D Tensor of shape [height, width, channels].
- new height: integer.
- new_width: integer.
- method: ResizeMethod. Defaults to ResizeMethod. BILINEAR.
- align_corners: bool. If true, exactly align all 4 cornets of the input and output. Defaults to false.

Raises:

- ValueError: if the shape of images is incompatible with the shape arguments to this function
- ValueError: if an unsupported resize method is specified.

Returns:

If images was 4-D, a 4-D float Tensor of shape [batch,

new height, new width, channels]. If images was 3-D, a 3-D float

Tensor of shape [new height, new_width, channels].

tf.image.resize_area(images, size, align_corners=None,
name=None)

Resize images to size using area interpolation.

Input images can be of different types but output images are always float.

Args:

images: A Tensor. Must be one of the following

types: uint8, int8, int16, int32, int64, float32, float64. **4-D** with shape [batch, height, width, channels].

- size: A 1-D int32 Tensor of 2 elements: new_height, new_width.
 The new size for the images.
- align_corners: An optional bool. Defaults to False. If true, rescale input by (new_height 1) / (height 1), which exactly aligns the 4 corners of images and resized images. If false, rescale by new_height / height. Treat similarly the width dimension.
- name: A name for the operation (optional).

Returns:

A Tensor of type float32. 4-D with shape [batch, new_height, new width, channels].

tf.image.resize_bicubic(images, size, align_corners=None,
name=None)

Resize images to size using bicubic interpolation.

Input images can be of different types but output images are always float.

Args:

• images: A Tensor. Must be one of the following

types: uint8, int8, int16, int32, int64, float32, float64. 4-D with shape [batch, height, width, channels].

- size: A 1-D int32 Tensor of 2 elements: new_height, new_width. The new size for the images.
- align_corners: An optional bool. Defaults to False. If true, rescale input by (new_height 1) / (height 1), which exactly aligns the 4 corners of images and resized images. If false, rescale by new_height / height. Treat similarly the width dimension.
- name: A name for the operation (optional).

Returns:

A Tensor of type float32. 4-D with shape [batch, new_height, new width, channels].

```
tf.image.resize_bilinear(images, size,
align corners=None, name=None)
```

Resize images to size using bilinear interpolation.

Input images can be of different types but output images are always float.

Args:

images: A Tensor. Must be one of the following

```
types: uint8, int8, int16, int32, int64, float32, float64. 4-D with shape [batch, height, width, channels].
```

- size: A 1-D int32 Tensor of 2 elements: new_height, new_width.

 The new size for the images.
- align_corners: An optional bool. Defaults to False. If true, rescale input by (new_height 1) / (height 1), which exactly aligns the 4 corners of images and resized images. If false, rescale by new_height / height. Treat similarly the width dimension.
- name: A name for the operation (optional).

Returns:

A Tensor of type float32. 4-D with shape [batch, new_height, new width, channels].

tf.image.resize_nearest_neighbor(images, size,
align corners=None, name=None)

Resize images to size using nearest neighbor interpolation.

Args:

images: A Tensor. Must be one of the following

```
types: uint8, int8, int16, int32, int64, float32, float64. 4-D with shape [batch, height, width, channels].
```

- size: A 1-D int32 Tensor of 2 elements: new_height, new_width.
 The new size for the images.
- align_corners: An optional bool. Defaults to False. If true, rescale input by (new_height 1) / (height 1), which exactly aligns the 4 corners of images and resized images. If false, rescale by new_height / height. Treat similarly the width dimension.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as images. 4-D with shape [batch, new height, new width, channels].

Cropping

```
tf.image.resize_image_with_crop_or_pad(image,
target_height, target_width)
```

Crops and/or pads an image to a target width and height.

Resizes an image to a target width and height by either centrally cropping the image or padding it evenly with zeros.

If width or height is greater than the

specified target_width or target_height respectively, this op centrally crops along that dimension. If width or height is smaller than the specified target_width ortarget_height respectively, this op centrally pads with 0 along that dimension.

Args:

- image: 3-D tensor of shape [height, width, channels]
- target height: Target height.
- target width: Target width.

Raises:

 ValueError: if target_height Or target_width are zero or negative.

Returns:

Cropped and/or padded image of shape [target_height,
target width, channels]

tf.image.pad_to_bounding_box(image, offset_height,
 offset_width, target_height, target_width)

Pad image with zeros to the specified height and width.

Adds offset_height rows of zeros on top, offset_width columns of zeros on the left, and then pads the image on the bottom and right with zeros until it has dimensions target height, target width.

This op does nothing if offset_* is zero and the image already has size target height by target width.

Args:

- image: 3-D tensor with shape [height, width, channels]
- offset height: Number of rows of zeros to add on top.
- offset width: Number of columns of zeros to add on the left.
- target height: Height of output image.
- target width: Width of output image.

Returns:

3-D tensor of shape [target_height, target_width, channels]

Raises:

ValueError: If the shape of image is incompatible with

the offset * or target * arguments

tf.image.crop_to_bounding_box(image, offset_height,
 offset_width, target_height, target_width)

Crops an image to a specified bounding box.

This op cuts a rectangular part out of image. The top-left corner of the returned image is at offset_height, offset_width in image, and its lower-right corner is at offset_height + target_height, offset_width + target_width.

Args:

- image: 3-D tensor with shape [height, width, channels]
- offset_height: Vertical coordinate of the top-left corner of the result in the input.
- offset_width: Horizontal coordinate of the top-left corner of the result in the input.
- target_height: Height of the result.
- target width: Width of the result.

Returns:

3-D tensor of image with shape [target_height, target_width, channels]

Raises:

ValueError: If the shape of image is incompatible with

the offset_* or target_* arguments

tf.image.extract_glimpse(input, size, offsets,
centered=None, normalized=None, uniform_noise=None,
name=None)

Extracts a glimpse from the input tensor.

Returns a set of windows called glimpses extracted at location offsets from the input tensor. If the windows only partially overlaps the inputs, the non overlapping areas will be filled with random noise.

The result is a 4-D tensor of shape [batch_size, glimpse_height, glimpse_width, channels]. The channels and batch dimensions are the same as that of the input tensor. The height and width of the output windows are specified in the size parameter.

The argument normalized and centered controls how the windows are built: * If the coordinates are normalized but not centered, 0.0 and 1.0 correspond to the minimum and maximum of each height and width dimension. * If the coordinates are both normalized and centered, they range from -1.0 to 1.0. The coordinates (-1.0, -1.0) correspond to the upper left corner, the lower right corner is located at (1.0, 1.0) and the center is at (0, 0). * If the coordinates are not normalized they are interpreted as numbers of pixels.

Args:

- input: A Tensor of type float32. A 4-D float tensor of shape [batch_size, height, width, channels].
- size: A Tensor of type int32. A 1-D tensor of 2 elements containing the size of the glimpses to extract. The glimpse height must be specified first, following by the glimpse width.
- offsets: A Tensor of type float32. A 2-D integer tensor of
 shape [batch_size, 2] containing the x, y locations of the center of each window.

- centered: An optional bool. Defaults to True. indicates if the offset coordinates are centered relative to the image, in which case the (0, 0) offset is relative to the center of the input images. If false, the (0,0) offset corresponds to the upper left corner of the input images.
- normalized: An optional bool. Defaults to True. indicates if the offset coordinates are normalized.
- uniform_noise: An optional bool. Defaults to True. indicates if the noise should be generated using a uniform distribution or a gaussian distribution.
- name: A name for the operation (optional).

Returns:

```
A Tensor of type float32. A tensor representing the glimpses [batch_size, glimpse_height, glimpse_width, channels].
```

Flipping and Transposing

```
tf.image.flip up down(image)
```

Flip an image horizontally (upside down).

Outputs the contents of image flipped along the first dimension, which is height.

See also reverse().

Args:

• image: A 3-D tensor of shape [height, width, channels].

Returns:

A 3-D tensor of the same type and shape as image.

Raises:

• ValueError: if the shape of image not supported.

```
tf.image.random flip up down(image, seed=None)
```

Randomly flips an image vertically (upside down).

With a 1 in 2 chance, outputs the contents of image flipped along the first dimension, which is height. Otherwise output the image as-is.

Args:

- image: A 3-D tensor of shape [height, width, channels].
- seed: A Python integer. Used to create a random seed.

See set random seed for behavior.

Returns:

A 3-D tensor of the same type and shape as image.

• ValueError: if the shape of image not supported.

```
tf.image.flip left right(image)
```

Flip an image horizontally (left to right).

Outputs the contents of ${\tt image}$ flipped along the second dimension,

which is width.

See also reverse ().

Args:

• image: A 3-D tensor of shape [height, width, channels].

Returns:

A 3-D tensor of the same type and shape as image.

Raises:

• ValueError: if the shape of image not supported.

```
tf.image.random flip left right(image, seed=None)
```

Randomly flip an image horizontally (left to right).

With a 1 in 2 chance, outputs the contents of image flipped along the second dimension, which is width. Otherwise output the image as-is.

Args:

- image: A 3-D tensor of shape [height, width, channels].
- seed: A Python integer. Used to create a random seed.

See set random seed for behavior.

Returns:

A 3-D tensor of the same type and shape as image.

Raises:

• ValueError: if the shape of image not supported.

```
tf.image.transpose image(image)
```

Transpose an image by swapping the first and second dimension.

See also transpose().

Args:

• image: 3-D tensor of shape [height, width, channels]

Returns:

A 3-D tensor of shape [width, height, channels]

Raises:

• ValueError: if the shape of image not supported.

Converting Between Colorspaces.

Image ops work either on individual images or on batches of images, depending on the shape of their input Tensor.

If 3-D, the shape is [height, width, channels], and the Tensor represents one image. If 4-D, the shape is [batch_size, height, width, channels], and the Tensor represents batch_size images.

Currently, channels can usefully be 1, 2, 3, or 4. Single-channel images are grayscale, images with 3 channels are encoded as either RGB or HSV. Images with 2 or 4 channels include an alpha channel, which has to be stripped from the image before passing the image to most image processing functions (and can be re-attached later). Internally, images are either stored in as one float32 per channel per pixel (implicitly, values are assumed to lie in [0,1)) or

one uint8 per channel per pixel (values are assumed to lie

Tensorflow can convert between images in RGB or HSV. The conversion functions work only on float images, so you need to convert images in other formats using convert image dtype.

Example:

in [0,255]).

```
# Decode an image and convert it to HSV.
rgb_image = tf.decode_png(..., channels=3)
rgb_image_float = tf.convert_image_dtype(rgb_image, tf.float32)
hsv_image = tf.rgb_to_hsv(rgb_image)
```

```
tf.image.rgb to grayscale(images)
```

Converts one or more images from RGB to Grayscale.

Outputs a tensor of the same DType and rank as images. The size of the last dimension of the output is 1, containing the Grayscale value of the pixels.

Args:

 images: The RGB tensor to convert. Last dimension must have size 3 and should contain RGB values.

Returns:

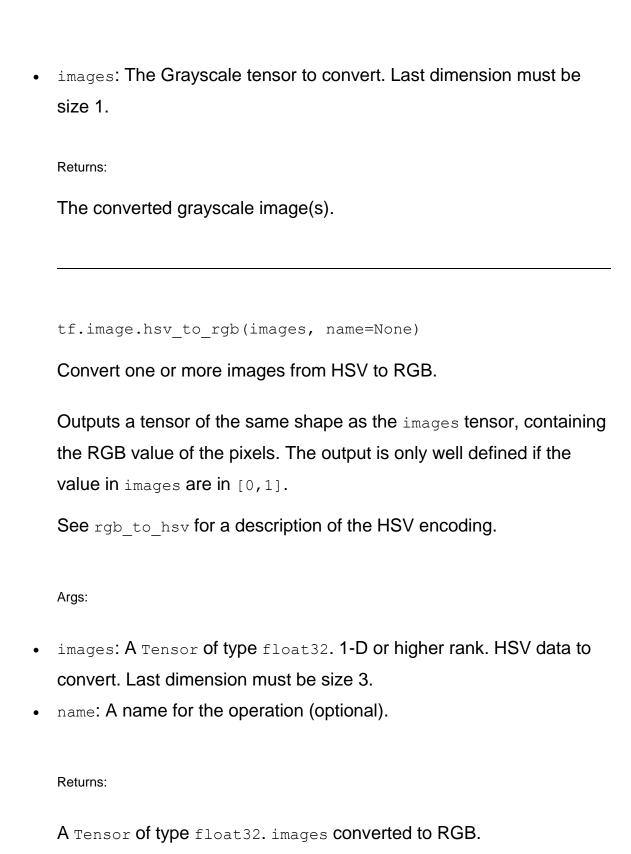

The converted grayscale image(s).

```
tf.image.grayscale to rgb(images)
```

Converts one or more images from Grayscale to RGB.

Outputs a tensor of the same DType and rank as images. The size of the last dimension of the output is 3, containing the RGB value of the pixels.

Args:

Converts one or more images from RGB to HSV.

Outputs a tensor of the same shape as the images tensor, containing the HSV value of the pixels. The output is only well defined if the value in images are in [0,1].

```
output[..., 0] contains hue, output[..., 1] contains saturation, and output[..., 2] contains value. All HSV values are in [0,1]. A hue of 0 corresponds to pure red, hue 1/3 is pure green, and 2/3 is pure blue.
```

Args:

- images: A Tensor of type float32. 1-D or higher rank. RGB data to convert. Last dimension must be size 3.
- name: A name for the operation (optional).

Returns:

A Tensor of type float32. images converted to HSV.

```
tf.image.convert_image_dtype(image, dtype,
saturate=False, name=None)
```

Convert image to dtype, scaling its values if needed.

Images that are represented using floating point values are expected to have values in the range [0,1). Image data stored in integer data types are expected to have values in the range [0, MAX],

where MAX is the largest positive representable number for the data type.

This op converts between data types, scaling the values appropriately before casting.

Note that converting from floating point inputs to integer types may lead to over/underflow problems. Set saturate to True to avoid such problem in problematic conversions. If enabled, saturation will clip the output into the allowed range before performing a potentially dangerous cast (and only before performing such a cast, i.e., when casting from a floating point to an integer type, and when casting from a signed to an unsigned type; saturatehas no effect on casts between floats, or on casts that increase the type's range).

Args:

- image: An image.
- dtype: A DType to convert image to.
- saturate: If True, clip the input before casting (if necessary).
- name: A name for this operation (optional).

Returns:

image, converted to dtype.

Image Adjustments

TensorFlow provides functions to adjust images in various ways: brightness, contrast, hue, and saturation. Each adjustment can be done with predefined parameters or with random parameters picked from predefined intervals. Random adjustments are often useful to expand a training set and reduce overfitting.

If several adjustments are chained it is advisable to minimize the number of redundant conversions by first converting the images to the most natural data type and representation (RGB or HSV). tf.image.adjust brightness(image, delta)

Adjust the brightness of RGB or Grayscale images.

This is a convenience method that converts an RGB image to float representation, adjusts its brightness, and then converts it back to the original data type. If several adjustments are chained it is advisable to minimize the number of redundant conversions.

The value delta is added to all components of the tensor image.

Both image and delta are converted tofloat before adding (and image is scaled appropriately if it is in fixed-point representation). For regular images, delta should be in the range [0,1), as it is added to the image in floating point representation, where pixel values are in the [0,1) range.

Args:

- image: A tensor.
- delta: A scalar. Amount to add to the pixel values.

Returns:

A brightness-adjusted tensor of the same shape and type as image.

Adjust the brightness of images by a random factor.

Equivalent to adjust_brightness() using a delta randomly picked in the interval [-max delta, max delta).

Args:

- image: An image.
- max delta: float, must be non-negative.
- seed: A Python integer. Used to create a random seed.

See set random seed for behavior.

Returns:

The brightness-adjusted image.

Raises:

• ValueError: if max_delta is negative.

```
tf.image.adjust contrast(images, contrast factor)
```

Adjust contrast of RGB or grayscale images.

This is a convenience method that converts an RGB image to float representation, adjusts its contrast, and then converts it back to the original data type. If several adjustments are chained it is advisable to minimize the number of redundant conversions. images is a tensor of at least 3 dimensions. The last 3 dimensions are interpreted as [height, width, channels]. The other dimensions only represent a collection of images, such as [batch, height, width, channels].

Contrast is adjusted independently for each channel of each image.

For each channel, this Op computes the mean of the image pixels in the channel and then adjusts each component x of each pixel to (x - x)

```
mean) * contrast factor + mean.
```

Args:

- images: Images to adjust. At least 3-D.
- contrast factor: A float multiplier for adjusting contrast.

Returns:

The constrast-adjusted image or images.

```
tf.image.random contrast(image, lower, upper, seed=None)
```

Adjust the contrast of an image by a random factor.

```
Equivalent to adjust_contrast() but uses
```

a contrast factor randomly picked in the interval [lower, upper].

Args:

- image: An image tensor with 3 or more dimensions.
- lower: float. Lower bound for the random contrast factor.
- upper: float. Upper bound for the random contrast factor.
- seed: A Python integer. Used to create a random seed.

```
See set random seed for behavior.
```

Returns:

The contrast-adjusted tensor.

Raises:

ValueError: if upper <= lower or if lower < 0.

```
tf.image.adjust hue(image, delta, name=None)
```

Adjust hue of an RGB image.

This is a convenience method that converts an RGB image to float representation, converts it to HSV, add an offset to the hue channel, converts back to RGB and then back to the original data type. If several adjustments are chained it is advisable to minimize the number of redundant conversions.

image is an RGB image. The image hue is adjusted by converting the image to HSV and rotating the hue channel (H) by delta. The image is then converted back to RGB.

```
delta must be in the interval [-1, 1].
```

Args:

- image: RGB image or images. Size of the last dimension must be 3.
- delta: float. How much to add to the hue channel.
- name: A name for this operation (optional).

Returns:

Adjusted image(s), same shape and DType as image.

```
tf.image.random hue(image, max delta, seed=None)
```

Adjust the hue of an RGB image by a random factor.

Equivalent to adjust_hue() but uses a delta randomly picked in the interval [-max_delta, max_delta].

max delta must be in the interval [0, 0.5].

Args:

- image: RGB image or images. Size of the last dimension must be 3.
- max_delta: float. Maximum value for the random delta.
- seed: An operation-specific seed. It will be used in conjunction with
 the graph-level seed to determine the real seeds that will be used in
 this operation. Please see the documentation of set_random_seed
 for its interaction with the graph-level random seed.

Returns:

3-D float tensor of shape [height, width, channels].

Raises:

• ValueError: if max delta is invalid.

tf.image.adjust_saturation(image, saturation_factor,
name=None)

Adjust saturation of an RGB image.

This is a convenience method that converts an RGB image to float representation, converts it to HSV, add an offset to the saturation channel, converts back to RGB and then back to the original data type. If several adjustments are chained it is advisable to minimize the number of redundant conversions.

image is an RGB image. The image saturation is adjusted by converting the image to HSV and multiplying the saturation (S) channel by saturation_factor and clipping. The image is then converted back to RGB.

Args:

- image: RGB image or images. Size of the last dimension must be 3.
- saturation factor: float. Factor to multiply the saturation by.
- name: A name for this operation (optional).

Returns:

Adjusted image(s), same shape and DType as image.

```
tf.image.random_saturation(image, lower, upper,
seed=None)
```

Adjust the saturation of an RGB image by a random factor.

```
Equivalent to adjust_saturation() but uses

a saturation_factor randomly picked in the interval[lower,
upper].
```

Args:

- image: RGB image or images. Size of the last dimension must be 3.
- lower: float. Lower bound for the random saturation factor.
- upper: float. Upper bound for the random saturation factor.
- seed: An operation-specific seed. It will be used in conjunction with
 the graph-level seed to determine the real seeds that will be used in
 this operation. Please see the documentation of set_random_seed
 for its interaction with the graph-level random seed.

Returns:

Adjusted image(s), same shape and DType as image.

Raises:

ValueError: if upper <= lower or if lower < 0.</p>

```
tf.image.per_image_whitening(image)
```

Linearly scales image to have zero mean and unit norm.

This op computes (x - mean) / adjusted_stddev, where mean is

the average of all values in image, and adjusted stddev =

```
max(stddev, 1.0/sqrt(image.NumElements())).
```

stddev is the standard deviation of all values in image. It is capped away from zero to protect against division by 0 when handling uniform images.

Note that this implementation is limited: * It only whitens based on the statistics of an individual image. * It does not take into account the covariance structure.

Args:

image: 3-D tensor of shape [height, width, channels].

Returns:

The whitened image with same shape as image.

Raises:

ValueError: if the shape of 'image' is incompatible with this function.

Working with Bounding Boxes

```
tf.image.draw_bounding_boxes(images, boxes, name=None)

Draw bounding boxes on a batch of images.
```

Outputs a copy of images but draws on top of the pixels zero or more bounding boxes specified by the locations in boxes. The coordinates of the each bounding box in boxes are encoded as[y_min, x_min, y_max, x_max]. The bounding box coordinates are floats in[0.0, 1.0]` relative to the width and height of the underlying image. For example, if an image is 100 x 200 pixels and the bounding box is [0.1, 0.5, 0.2, 0.9], the bottom-left and upper-right coordinates of the bounding box will be (10, 40) to (50, 180).

Parts of the bounding box may fall outside the image.

Args:

- images: A Tensor of type float32. 4-D with shape [batch, height, width, depth]. A batch of images.
- boxes: A Tensor of type float32. 3-D with shape [batch,
 num bounding boxes, 4] containing bounding boxes.
- name: A name for the operation (optional).

Returns:

A Tensor of type float32. 4-D with the same shape as images. The batch of input images with bounding boxes drawn on the images.

```
tf.image.sample_distorted_bounding_box(image_size,
bounding_boxes, seed=None, seed2=None,
min_object_covered=None, aspect_ratio_range=None,
area_range=None, max_attempts=None,
use image if no bounding boxes=None, name=None)
```

Generate a single randomly distorted bounding box for an image.

Bounding box annotations are often supplied in addition to ground-truth labels in image recognition or object localization tasks. A common technique for training such a system is to randomly distort an image while preserving its content, i.e. data augmentation. This Op outputs a randomly distorted localization of an object, i.e.

bounding box, given an image_size, bounding_boxes and a series of constraints.

The output of this Op is a single bounding box that may be used to crop the original image. The output is returned as 3

tensors: begin, size and bboxes. The first 2 tensors can be fed

directly into tf.slice to crop the image. The latter may be supplied

to tf.image.draw_bounding_box to visualize what the bounding box looks like.

Bounding boxes are supplied and returned as [y min, x min,

 y_{max} , x_{max}]. The bounding box coordinates are floats in [0.0,

1.0] relative to the width and height of the underlying image.

For example,

```
# Employ the bounding box to distort the image.
distorted_image = tf.slice(image, begin, size)
```

Note that if no bounding box information is available,

setting use_image_if_no_bounding_boxes = truewill assume there is a single implicit bounding box covering the whole image.

If use_image_if_no_bounding_boxes is false and no bounding boxes are supplied, an error is raised.

Args:

- image_size: A Tensor. Must be one of the following
 types: uint8, int8, int16, int32, int64. 1-D, containing [height, width, channels].
- bounding_boxes: A Tensor of type float32. 3-D with shape [batch,
 N, 4] describing the N bounding boxes associated with the image.
- seed: An optional int. Defaults to 0. If either seed or seed2 are set to non-zero, the random number generator is seeded by the given seed.
 Otherwise, it is seeded by a random seed.
- seed2: An optional int. Defaults to 0. A second seed to avoid seed collision.
- min_object_covered: An optional float. Defaults to 0.1. The cropped area of the image must contain at least this fraction of any bounding box supplied.
- aspect_ratio_range: An optional list of floats. Defaults to [0.75, 1.33]. The cropped area of the image must have an aspect ratio = width / height within this range.

- area_range: An optional list of floats. Defaults to [0.05, 1]. The cropped area of the image must contain a fraction of the supplied image within in this range.
- max_attempts: An optional int. Defaults to 100. Number of attempts
 at generating a cropped region of the image of the specified
 constraints. After max attempts failures, return the entire image.
- use_image_if_no_bounding_boxes: An optional bool. Defaults
 to False. Controls behavior if no bounding boxes supplied. If true,
 assume an implicit bounding box covering the whole input. If false,
 raise an error.
- name: A name for the operation (optional).

Returns:

A tuple of Tensor objects (begin, size, bboxes).

- begin: A Tensor. Has the same type as image_size. 1-D,
 containing [offset_height, offset_width, 0]. Provide as input
 to tf.slice.
- size: A Tensor. Has the same type as image_size. 1-D,
 containing [target_height, target_width, -1]. Provide as input
 to tf.slice.
- bboxes: A Tensor of type float32. 3-D with shape [1, 1, 4] containing the distorted bounding box. Provide as input
 to tf.image.draw_bounding_boxes.

Other Functions and Classes

```
tf.image.saturate cast(image, dtype)
```

Performs a safe cast of image data to dtype.

This function casts the data in image to dtype, without applying any scaling. If there is a danger that image data would over or underflow in the cast, this op applies the appropriate clamping before the cast.

Args:

- image: An image to cast to a different data type.
- dtype: A DType to cast image to.

Returns:

image, safely cast to dtype.

Sparse Tensors

Note: Functions taking Tensor arguments can also take anything

```
accepted by tf.convert to tensor.
```

Sparse Tensor Representation

Tensorflow supports a SparseTensor representation for data that is sparse in multiple dimensions. Contrast this representation with IndexedSlices, which is efficient for representing tensors that are sparse in their first dimension, and dense along all other dimensions.

```
class tf.SparseTensor
```

Represents a sparse tensor.

Tensorflow represents a sparse tensor as three separate dense tensors: indices, values, and shape. In Python, the three tensors are collected into a SparseTensor class for ease of use. If you have separate indices, values, and shape tensors, wrap them in a SparseTensor object before passing to the ops below.

Concretely, the sparse tensor SparseTensor (indices, values, shape) is

indices: A 2-D int64 tensor of shape [N, ndims].

- values: A 1-D tensor of any type and shape [N].
- shape: A 1-D int64 tensor of shape [ndims].
 where N and ndims are the number of values, and number of dimensions in the SparseTensor respectively.

The corresponding dense tensor satisfies

```
dense.shape = shape
dense[tuple(indices[i])] = values[i]
```

By convention, indices should be sorted in row-major order (or equivalently lexicographic order on the tuplesindices[i]). This is not enforced when SparseTensor objects are constructed, but most ops assume correct ordering. If the ordering of sparse tensor st is wrong, a fixed version can be obtained by

```
callingtf.sparse_reorder(st).
```

Example: The sparse tensor

```
SparseTensor(indices=[[0, 0], [1, 2]], values=[1, 2], shape=[3,
4])
```

represents the dense tensor

```
[[1, 0, 0, 0]
[0, 0, 2, 0]
[0, 0, 0, 0]]
```

```
tf.SparseTensor.__init__(indices, values, shape)
```

Creates a SparseTensor.

Args:

• indices: A 2-D int64 tensor of shape [N, ndims].

values: A 1-D tensor of any type and shape [N].

shape: A 1-D int64 tensor of shape [ndims].

Returns:

A SparseTensor

tf.SparseTensor.indices

The indices of non-zero values in the represented dense tensor.

Returns:

A 2-D Tensor of int64 with shape [N, ndims], where N is the number of non-zero values in the tensor, and ndims is the rank.

tf.SparseTensor.values

The non-zero values in the represented dense tensor.

Returns:

A 1-D Tensor of any data type.

tf.SparseTensor.dtype The DType of elements in this tensor. tf.SparseTensor.shape A 1-D Tensor of int64 representing the shape of the dense tensor. tf.SparseTensor.graph The Graph that contains the index, value, and shape tensors. class tf.SparseTensorValue SparseTensorValue(indices, values, shape) tf.SparseTensorValue.indices Alias for field number 0 tf.SparseTensorValue.shape

```
tf.SparseTensorValue.values
```

Alias for field number 1

Sparse to Dense Conversion

```
tf.sparse_to_dense(sparse_indices, output_shape,
sparse_values, default_value=0, validate_indices=True,
name=None)
```

Converts a sparse representation into a dense tensor.

Builds an array dense with shape output shape such that

```
# If sparse_indices is scalar
dense[i] = (i == sparse_indices ? sparse_values : default_value)

# If sparse_indices is a vector, then for each i
dense[sparse_indices[i]] = sparse_values[i]

# If sparse_indices is an n by d matrix, then for each i in [0,
n)
dense[sparse_indices[i][0], ..., sparse_indices[i][d-1]] =
sparse_values[i]
```

All other values in dense are set to default value.

If sparse_values is a scalar, all sparse indices are set to this single value.

Indices should be sorted in lexicographic order, and indices must not contain any repeats. If validate_indices is True, these properties are checked during execution.

Args:

- sparse_indices: A 0-D, 1-D, or 2-D Tensor of type int32 or int64. sparse_indices[i] contains the complete index where sparse values[i] will be placed.
- output_shape: A 1-D Tensor of the same type as sparse_indices.
 Shape of the dense output tensor.
- sparse_values: A 0-D or 1-D Tensor. Values corresponding to each row of sparse_indices, or a scalar value to be used for all sparse indices.
- default_value: A 0-D Tensor of the same type as sparse_values.
 Value to set for indices not specified in sparse_indices. Defaults to zero.
- validate_indices: A boolean value. If True, indices are checked to make sure they are sorted in lexicographic order and that there are no repeats.
- name: A name for the operation (optional).

Returns:

Dense Tensor of shape output_shape. Has the same type as sparse values.

tf.sparse_tensor_to_dense(sp_input, default_value=0,
validate indices=True, name=None)

Converts a SparseTensor into a dense tensor.

This op is a convenience wrapper

around sparse_to_dense for SparseTensorS.

For example, if sp_input has shape [3, 5] and non-empty string values:

```
[0, 1]: a
[0, 3]: b
[2, 0]: c
```

and default value is x, then the output will be a dense [3,

5] string tensor with values:

```
[[x a x b x]
[x x x x x]
[c x x x x]]
```

Indices must be without repeats. This is only tested if validate_indices is True.

Args:

- sp input: The input SparseTensor.
- default_value: Scalar value to set for indices not specified
 in sp_input. Defaults to zero.
- validate_indices: A boolean value. If True, indices are checked to make sure they are sorted in lexicographic order and that there are no repeats.
- name: A name prefix for the returned tensors (optional).

Returns:

A dense tensor with shape <code>sp_input.shape</code> and values specified by the non-empty values in <code>sp_input</code>. Indices not in <code>sp_input</code> are assigned <code>default_value</code>.

Raises:

• TypeError: If sp_input is not a SparseTensor.

```
tf.sparse_to_indicator(sp_input, vocab_size, name=None)
Converts a SparseTensor of ids into a dense bool indicator tensor.
The last dimension of sp_input is discarded and replaced with the
values of sp_input. If sp_input.shape = [D0, D1, ..., Dn, K],
then output.shape = [D0, D1, ..., Dn, vocab_size], where
output[d_0, d_1, ..., d_n, sp_input[d_0, d_1, ..., d_n, k]] =
True
```

and False elsewhere in output.

For example, if sp_input.shape = [2, 3, 4] with non-empty values:

```
[0, 0, 0]: 0

[0, 1, 0]: 10

[1, 0, 3]: 103

[1, 1, 2]: 150

[1, 1, 4]: 150

[1, 2, 1]: 121
```

and vocab_size = 200, then the output will be a [2, 3, 200] dense bool tensor with False everywhere except at positions

```
(0, 0, 0), (0, 1, 10), (1, 0, 103), (1, 1, 149), (1, 1, 150),
(1, 2, 121).
```

Note that repeats are allowed in the input SparseTensor. This op is useful for converting SparseTensors into dense formats for compatibility with ops that expect dense tensors.

The input SparseTensor must be in row-major order.

- sp_input: A SparseTensor of type int32 or int64.
- vocab_size: The new size of the last dimension, with all(0 <= sp_input.values < vocab_size).
- name: A name prefix for the returned tensors (optional)

Returns:

A dense bool indicator tensor representing the indices with specified value.

Raises:

• TypeError: If sp input is not a SparseTensor.

Manipulation

```
tf.sparse concat(concat dim, sp inputs, name=None)
```

Concatenates a list of SparseTensor along the specified dimension. Concatenation is with respect to the dense versions of each sparse input. It is assumed that each inputs is asparseTensor whose elements are ordered along increasing dimension number. All inputs' shapes must match, except for the concat dimension.

The indices, values, and shapes lists must have the same length.

The output shape is identical to the inputs', except along the concat dimension, where it is the sum of the inputs' sizes along that dimension.

The output elements will be resorted to preserve the sort order along increasing dimension number.

This op runs in $O(M \log M)$ time, where M is the total number of non-empty values across all inputs. This is due to the need for an internal sort in order to concatenate efficiently across an arbitrary dimension.

For example, if concat dim = 1 and the inputs are

```
sp_inputs[0]: shape = [2, 3]
[0, 2]: "a"
[1, 0]: "b"
[1, 1]: "c"

sp_inputs[1]: shape = [2, 4]
[0, 1]: "d"
[0, 2]: "e"
```

then the output will be

```
shape = [2, 7]
[0, 2]: "a"
[0, 4]: "d"
[0, 5]: "e"
[1, 0]: "b"
[1, 1]: "c"
```

Graphically this is equivalent to doing

```
[ a] concat [ d e ] = [ a d e ]
[b c ] [ ] [b c ]
```

Args:

- concat dim: Dimension to concatenate along.
- sp_inputs: List of SparseTensor to concatenate.
- name: A name prefix for the returned tensors (optional).

Returns:

A SparseTensor with the concatenated output.

Raises:

• TypeError: If sp_inputs is not a list of SparseTensor.

```
tf.sparse_reorder(sp_input, name=None)
```

Reorders a SparseTensor into the canonical, row-major ordering.

Note that by convention, all sparse ops preserve the canonical ordering along increasing dimension number. The only time ordering can be violated is during manual manipulation of the indices and values to add entries.

Reordering does not affect the shape of the SparseTensor.

For example, if sp_input has shape [4, 5] and indices / values:

```
[0, 3]: b
[0, 1]: a
[3, 1]: d
[2, 0]: c
```

then the output will be a SparseTensor of shape [4,

5] and indices / values:

```
[0, 1]: a
[0, 3]: b
[2, 0]: c
[3, 1]: d
```

Args:

sp input: The input SparseTensor.

name: A name prefix for the returned tensors (optional)

Returns:

A sparseTensor with the same shape and non-empty values, but in canonical ordering.

Raises:

TypeError: If sp input is not a SparseTensor.

```
tf.sparse_split(split_dim, num_split, sp_input,
name=None)

Split a SparseTensor into num_split tensors along split_dim.

If the sp_input.shape[split_dim] is not an integer multiple

of num_split each slice starting from 0:shape[split_dim] %

num_split gets extra one dimension. For example, if split_dim =

1 andnum_split = 2 and the input is:
input_tensor = shape = [2, 7]
[ a de ]
[b c ]
```

Graphically the output tensors are:

- split_dim: A 0-D int32 Tensor. The dimension along which to split.
- num split: A Python integer. The number of ways to split.
- sp input: The SparseTensor to split.
- name: A name for the operation (optional).

Returns:

num split SparseTensor objects resulting from splitting value.

Raises:

• TypeError: If sp input is not a SparseTensor.

```
tf.sparse retain(sp input, to retain)
```

Retains specified non-empty values within a SparseTensor.

For example, if sp_input has shape [4, 5] and 4 non-empty string values:

```
[0, 1]: a
[0, 3]: b
[2, 0]: c
[3, 1]: d
```

and to_retain = [True, False, False, True], then the output

will be a SparseTensor of shape [4, 5] with 2 non-empty values:

```
[0, 1]: a
[3, 1]: d
```

- sp_input: The input SparseTensor with N non-empty elements.
- to retain: A bool vector of length N with M true values.

Returns:

A SparseTensor with the same shape as the input and M non-empty elements corresponding to the true positions in to_retain.

Raises:

TypeError: If sp input is not a SparseTensor.

```
tf.sparse_fill_empty_rows(sp_input, default_value,
name=None)
```

Fills empty rows in the input 2-D SparseTensor with a default value.

This op adds entries with the specified default_value at

index [row, 0] for any row in the input that does not already have a value.

For example, suppose sp_input has shape [5, 6] and non-empty values:

```
[0, 1]: a
[0, 3]: b
[2, 0]: c
[3, 1]: d
```

Rows 1 and 4 are empty, so the output will be of shape [5, 6] with values:

```
[0, 1]: a
```

```
[0, 3]: b
[1, 0]: default_value
[2, 0]: c
[3, 1]: d
[4, 0]: default_value
```

Note that the input may have empty columns at the end, with no effect on this op.

The output SparseTensor will be in row-major order and will have the same shape as the input.

This op also returns an indicator vector such that

```
empty_row_indicator[i] = True iff row i was an empty row.
```

Args:

- sp input: A SparseTensor with shape [N, M].
- default_value: The value to fill for empty rows, with the same type
 as sp input.
- name: A name prefix for the returned tensors (optional)

Returns:

- sp_ordered_output: A SparseTensor with shape [N, M], and with all empty rows filled in withdefault_value.
- empty_row_indicator: A bool vector of length N indicating whether
 each input row was empty.

Raises:

• TypeError: If sp input is not a SparseTensor.

- tf.train.shuffle_batch_join(tensor_list_list, batch_size, capacity, min_after_dequeue, seed=None, enqueue many=False, shapes=None, name=None)

Placeholders

TensorFlow provides a placeholder operation that must be fed with data on execution. For more info, see the section on <u>Feeding data</u>.

```
tf.placeholder(dtype, shape=None, name=None)
```

Inserts a placeholder for a tensor that will be always fed.

Important: This tensor will produce an error if evaluated. Its value must be fed using the feed dict optional argument

```
to Session.run(), Tensor.eval(), Or Operation.run().
```

For example:

```
x = tf.placeholder(tf.float32, shape=(1024, 1024))
```

```
y = tf.matmul(x, x)
with tf.Session() as sess:
  print(sess.run(y)) # ERROR: will fail because x was not fed.

rand_array = np.random.rand(1024, 1024)
  print(sess.run(y, feed dict={x: rand array})) # Will succeed.
```

- dtype: The type of elements in the tensor to be fed.
- shape: The shape of the tensor to be fed (optional). If the shape is not specified, you can feed a tensor of any shape.
- name: A name for the operation (optional).

Returns:

A Tensor that may be used as a handle for feeding a value, but not evaluated directly.

Readers

TensorFlow provides a set of Reader classes for reading data formats. For more information on inputs and readers, see <u>Reading</u> <u>data</u>.

```
class tf.ReaderBase
```

Base class for different Reader types, that produce a record every step.

Conceptually, Readers convert string 'work units' into records (key, value pairs). Typically the 'work units' are filenames and the records

are extracted from the contents of those files. We want a single record produced per step, but a work unit can correspond to many records.

Therefore we introduce some decoupling using a queue. The queue contains the work units and the Reader dequeues from the queue when it is asked to produce a record (via Read()) but it has finished the last work unit.

```
tf.ReaderBase.__init__(reader_ref,
supports serialize=False)
```

Creates a new ReaderBase.

Args:

- reader ref: The operation that implements the reader.
- supports_serialize: True if the reader implementation can serialize its state.

```
tf.ReaderBase.num records produced(name=None)
```

Returns the number of records this reader has produced.

This is the same as the number of Read executions that have succeeded.

Args:

name: A name for the operation (optional).

Returns:
An int64 Tensor.
tf.ReaderBase.num_work_units_completed(name=None)
Returns the number of work units this reader has finished processing.
Args:
name: A name for the operation (optional).
Returns:
An int64 Tensor.
tf.ReaderBase.read(queue, name=None)
Returns the next record (key, value pair) produced by a reader.
Will dequeue a work unit from queue if necessary (e.g. when the Reader needs to start reading from a new file since it has finished with the previous file).

- queue: A Queue or a mutable string Tensor representing a handle to a Queue, with string work items.
- name: A name for the operation (optional).

Returns: A tuple of Tensors (key, value). • key: A string scalar Tensor. • value: A string scalar Tensor. tf.ReaderBase.reader ref Op that implements the reader. tf.ReaderBase.reset(name=None) Restore a reader to its initial clean state. Args: name: A name for the operation (optional). Returns: The created Operation. tf.ReaderBase.restore_state(state, name=None)

Restore a reader to a previously saved state.

	Unimplemented error.
	Args:
•	state: A string Tensor. Result of a SerializeState of a Reader with matching type. name: A name for the operation (optional).
	Returns:
	The created Operation.
	tf.ReaderBase.serialize_state(name=None)
	Produce a string tensor that encodes the state of a reader.
	Not all Readers support being serialized, so this can produce an Unimplemented error.
	Args:
•	name: A name for the operation (optional).
	Returns:
	A string Tensor.
	tf.ReaderBase.supports_serialize

Not all Readers support being restored, so this can produce an

Whether the Reader implementation can serialize its state.

class tf.TextLineReader

A Reader that outputs the lines of a file delimited by newlines.

Newlines are stripped from the output. See ReaderBase for supported methods.

```
tf.TextLineReader.__init__(skip_header_lines=None,
name=None)
```

Create a TextLineReader.

Args:

- skip_header_lines: An optional int. Defaults to 0. Number of lines to skip from the beginning of every file.
- name: A name for the operation (optional).

```
tf.TextLineReader.num records produced(name=None)
```

Returns the number of records this reader has produced.

This is the same as the number of Read executions that have succeeded.

Args:

name: A name for the operation (optional).
Returns:
An int64 Tensor.
tf.TextLineReader.num_work_units_completed(name=None)
Returns the number of work units this reader has finished processing
Args:
name: A name for the operation (optional).
Returns:
An int64 Tensor.
tf.TextLineReader.read(queue, name=None)
Returns the next record (key, value pair) produced by a reader.
Will dequeue a work unit from queue if necessary (e.g. when the Reader needs to start reading from a new file since it has finished with the previous file).
Args:
gueue: A Queue or a mutable string Tensor representing a handle to

a Queue, with string work items.

•	name: A name for the operation (optional).
	Returns:
	A tuple of Tensors (key, value).
•	key: A string scalar Tensor.
•	value: A string scalar Tensor.
	tf.TextLineReader.reader_ref
	Op that implements the reader.
	tf.TextLineReader.reset(name=None)
	Restore a reader to its initial clean state.
	Args:
•	name: A name for the operation (optional).
	Returns:
	The created Operation.
	<pre>tf.TextLineReader.restore_state(state, name=None)</pre>

Restore a reader to a previously saved state. Not all Readers support being restored, so this can produce an Unimplemented error. Args: state: A string Tensor. Result of a SerializeState of a Reader with matching type. name: A name for the operation (optional). Returns: The created Operation. tf.TextLineReader.serialize state(name=None) Produce a string tensor that encodes the state of a reader. Not all Readers support being serialized, so this can produce an Unimplemented error. Args: name: A name for the operation (optional). Returns: A string Tensor.

```
tf.TextLineReader.supports serialize
```

Whether the Reader implementation can serialize its state.

```
class tf.WholeFileReader
```

A Reader that outputs the entire contents of a file as a value.

To use, enqueue filenames in a Queue. The output of Read will be a filename (key) and the contents of that file (value).

See ReaderBase for supported methods.

```
tf.WholeFileReader.__init__(name=None)
```

Create a WholeFileReader.

Args:

name: A name for the operation (optional).

```
tf.WholeFileReader.num records produced(name=None)
```

Returns the number of records this reader has produced.

This is the same as the number of Read executions that have succeeded.

Args:

name: A name for the operation (optional).
Returns:
An int64 Tensor.
tf.WholeFileReader.num_work_units_completed(name=None)
Returns the number of work units this reader has finished processing.
Args:
name: A name for the operation (optional).
Returns:
An int64 Tensor.
+6 Mb - la Tilla Danadan and addan and Maran
tf.WholeFileReader.read(queue, name=None)
Returns the next record (key, value pair) produced by a reader.
Will dequeue a work unit from queue if necessary (e.g. when the Reader needs to start reading from a new file since it has finished with the previous file).
Args:
gueue: A Queue or a mutable string Tensor representing a handle to

a Queue, with string work items.

•	name: A name for the operation (optional).
	Returns:
	A tuple of Tensors (key, value).
•	key: A string scalar Tensor.
•	value: A string scalar Tensor.
	tf.WholeFileReader.reader ref
	Op that implements the reader.
	tf.WholeFileReader.reset(name=None)
	Restore a reader to its initial clean state.
	Args:
•	name: A name for the operation (optional).
	Returns:
	The created Operation.
	tf.WholeFileReader.restore_state(state, name=None)

Restore a reader to a previously saved state. Not all Readers support being restored, so this can produce an Unimplemented error. Args: state: A string Tensor. Result of a SerializeState of a Reader with matching type. name: A name for the operation (optional). Returns: The created Operation. tf.WholeFileReader.serialize state(name=None) Produce a string tensor that encodes the state of a reader. Not all Readers support being serialized, so this can produce an Unimplemented error. Args: name: A name for the operation (optional). Returns: A string Tensor.

```
tf.WholeFileReader.supports serialize
```

Whether the Reader implementation can serialize its state.

```
class tf. Identity Reader
```

A Reader that outputs the queued work as both the key and value.

To use, enqueue strings in a Queue. Read will take the front work string and output (work, work).

See ReaderBase for supported methods.

```
tf.IdentityReader. init (name=None)
```

Create a IdentityReader.

Args:

name: A name for the operation (optional).

```
tf.IdentityReader.num records produced(name=None)
```

Returns the number of records this reader has produced.

This is the same as the number of Read executions that have succeeded.

Args:

name: A name for the operation (optional).
Returns:
An int64 Tensor.
tf.IdentityReader.num work units completed(name=None)
Returns the number of work units this reader has finished processing
Args:
name: A name for the operation (optional).
Returns:
An int64 Tensor.
tf.IdentityReader.read(queue, name=None)
Returns the next record (key, value pair) produced by a reader.
Will dequeue a work unit from queue if necessary (e.g. when the Reader needs to start reading from a new file since it has finished with the previous file).
Args:
queue: A Queue or a mutable string Tensor representing a handle to

a Queue, with string work items.

•	name: A name for the operation (optional).
	Returns:
	A tuple of Tensors (key, value).
•	key: A string scalar Tensor.
•	value: A string scalar Tensor.
	tf.IdentityReader.reader_ref
	Op that implements the reader.
	tf.IdentityReader.reset(name=None)
	Restore a reader to its initial clean state.
	Args:
•	name: A name for the operation (optional).
-	name. A marile for the operation (optional).
	Returns:
	The created Operation.
	<pre>tf.IdentityReader.restore_state(state, name=None)</pre>

Restore a reader to a previously saved state. Not all Readers support being restored, so this can produce an Unimplemented error. Args: state: A string Tensor. Result of a SerializeState of a Reader with matching type. name: A name for the operation (optional). Returns: The created Operation. tf.IdentityReader.serialize state(name=None) Produce a string tensor that encodes the state of a reader. Not all Readers support being serialized, so this can produce an Unimplemented error. Args: name: A name for the operation (optional). Returns: A string Tensor.

```
tf.IdentityReader.supports serialize
 Whether the Reader implementation can serialize its state.
 class tf.TFRecordReader
 A Reader that outputs the records from a TFRecords file.
 See ReaderBase for supported methods.
 tf.TFRecordReader.__init__(name=None)
 Create a TFRecordReader.
 Args:
name: A name for the operation (optional).
 tf.TFRecordReader.num records produced(name=None)
 Returns the number of records this reader has produced.
 This is the same as the number of Read executions that have
 succeeded.
 Args:
```

• name: A name for the operation (optional).

Returns:
An int64 Tensor.
tf.TFRecordReader.num_work_units_completed(name=None)
Returns the number of work units this reader has finished processing
Argo
Args:
name: A name for the operation (optional).
Returns:
An int64 Tensor.
tf.TFRecordReader.read(queue, name=None)
Returns the next record (key, value pair) produced by a reader.
Will dequeue a work unit from queue if necessary (e.g. when the Reader needs to start reading from a new file since it has finished

with the previous file).

- queue: A Queue or a mutable string Tensor representing a handle to a Queue, with string work items.
- name: A name for the operation (optional).

A tuple of Tensors (key, value). • key: A string scalar Tensor. • value: A string scalar Tensor. tf.TFRecordReader.reader ref Op that implements the reader. tf.TFRecordReader.reset(name=None) Restore a reader to its initial clean state. Args: name: A name for the operation (optional). Returns: The created Operation. tf.TFRecordReader.restore_state(state, name=None)

Restore a reader to a previously saved state.

Returns:

Not all Readers support being restored, so this can produce an Unimplemented error.
Args:
state: A string Tensor. Result of a SerializeState of a Reader with
name: A name for the operation (optional).
Returns:
The created Operation.
tf.TFRecordReader.serialize_state(name=None)
Produce a string tensor that encodes the state of a reader.
Not all Readers support being serialized, so this can produce an Unimplemented error.
Args:
name: A name for the operation (optional).
Returns:
A string Tensor.
tf.TFRecordReader.supports serialize
cr.trvecoraveader.pabborcp_perrarrye

Whether the Reader implementation can serialize its state.

```
class tf.FixedLengthRecordReader
```

A Reader that outputs fixed-length records from a file.

See ReaderBase for supported methods.

```
tf.FixedLengthRecordReader.__init__(record_bytes,
header bytes=None, footer bytes=None, name=None)
```

Create a FixedLengthRecordReader.

Args:

- record bytes: An int.
- header bytes: An optional int. Defaults to 0.
- footer bytes: An optional int. Defaults to 0.
- name: A name for the operation (optional).

```
tf.FixedLengthRecordReader.num_records_produced(name=None)
```

Returns the number of records this reader has produced.

This is the same as the number of Read executions that have succeeded.

	Args:
•	name: A name for the operation (optional).
	Returns:
	An int64 Tensor.
	<pre>tf.FixedLengthRecordReader.num_work_units_completed(name= None)</pre>
	Returns the number of work units this reader has finished processing.
	Args:
•	name: A name for the operation (optional).
	Returns:
	An int64 Tensor.
	tf.FixedLengthRecordReader.read(queue, name=None)
	Returns the next record (key, value pair) produced by a reader.
	Will dequeue a work unit from queue if necessary (e.g. when the Reader needs to start reading from a new file since it has finished with the previous file).
	Args:

queue: A Queue or a mutable string Tensor representing a handle to
a Queue, with string work items.
name: A name for the operation (optional).
Returns:
A tuple of Tensors (key, value).
key: A string scalar Tensor.
value: A string scalar Tensor.
tf.FixedLengthRecordReader.reader_ref
Op that implements the reader.
tf.FixedLengthRecordReader.reset(name=None)
Restore a reader to its initial clean state.
Args:
name: A name for the operation (optional).
name. A name for the operation (optional).
Deturne
Returns:
The created Operation.

•

•

•

```
tf.FixedLengthRecordReader.restore state(state,
   name=None)
   Restore a reader to a previously saved state.
   Not all Readers support being restored, so this can produce an
   Unimplemented error.
   Args:
• state: A string Tensor. Result of a SerializeState of a Reader with
   matching type.
  name: A name for the operation (optional).
   Returns:
   The created Operation.
   tf.FixedLengthRecordReader.serialize state(name=None)
   Produce a string tensor that encodes the state of a reader.
  Not all Readers support being serialized, so this can produce an
   Unimplemented error.
   Args:
 name: A name for the operation (optional).
   Returns:
  A string Tensor.
```

```
tf.FixedLengthRecordReader.supports serialize
```

Whether the Reader implementation can serialize its state.

Converting

TensorFlow provides several operations that you can use to convert various data formats into tensors.

```
tf.decode_csv(records, record_defaults, field_delim=None,
name=None)
```

Convert CSV records to tensors. Each column maps to one tensor.

RFC 4180 format is expected for the CSV records. (https://tools.ietf.org/html/rfc4180) Note that we allow leading and trailing spaces with int or float field.

Args:

- records: A Tensor of type string. Each string is a record/row in the csv and all records should have the same format.
- record_defaults: A list of Tensor objects with types

from: float32, int32, int64, string. One tensor per column of the input record, with either a scalar default value for that column or empty if the column is required.

- field_delim: An optional string. Defaults to ", ". delimiter to separate fields in a record.
- name: A name for the operation (optional).

Returns:

A list of Tensor objects. Has the same type as record_defaults. Each tensor will have the same shape as records.

```
tf.decode_raw(bytes, out_type, little_endian=None,
name=None)
```

Reinterpret the bytes of a string as a vector of numbers.

Args:

- bytes: A Tensor of type string. All the elements must have the same length.
- out_type: A tf.DType from: tf.float32, tf.float64, tf.int32, tf.uint8, tf.int16, tf.int8, tf.int64.
- little_endian: An optional bool. Defaults to True. Whether the input bytes are in little-endian order. Ignored for out_type values that are stored in a single byte like uint8.
- name: A name for the operation (optional).

Returns:

A Tensor of type out_type. A Tensor with one more dimension than the input bytes. The added dimension will have size equal to the length of the elements of bytes divided by the number of bytes to representout type.

Example protocol buffer

TensorFlow's <u>recommended format for training examples</u> is serialized Example protocol buffers, <u>described here</u>. They contain Features, <u>described here</u>.

class tf. VarLen Feature

Configuration for parsing a variable-length input feature.

Fields: dtype: Data type of input.

tf.VarLenFeature.dtype

Alias for field number 0

class tf.FixedLenFeature

Configuration for parsing a fixed-length input feature.

To treat sparse input as dense, provide a <code>default_value</code>; otherwise, the parse functions will fail on any examples missing this feature. Fields: shape: Shape of input data. dtype: Data type of input. default_value: Value to be used if an example is missing this feature. It must be compatible with <code>dtype</code>.

tf.FixedLenFeature.default value

Alias for field number 2

tf.FixedLenFeature.dtype

Alias for field number 1

tf.FixedLenFeature.shape

Alias for field number 0

class tf.FixedLenSequenceFeature

Configuration for a dense input feature in a sequence item.

To treat a sparse input as dense, provide allow_missing=True; otherwise, the parse functions will fail on any examples missing this feature.

Fields: shape: Shape of input data. dtype: Data type of input. allow_missing: Whether to allow this feature to be missing from a feature list item.

Alias for field number 2

tf.FixedLenSequenceFeature.dtype

Alias for field number 1

tf.FixedLenSequenceFeature.shape

Alias for field number 0

tf.parse_example(serialized, features, name=None,
example_names=None)

Parses Example protos into a dict of tensors.

Parses a number of serialized Example protos given in serialized.

example_names may contain descriptive names for the corresponding serialized protos. These may be useful for debugging purposes, but they have no effect on the output. If not None, example_names must be the same length as serialized.

This op parses serialized examples into a dictionary mapping keys to Tensor and SparseTensor objects.features is a dict from keys

to $\mbox{VarLenFeature}$ and $\mbox{FixedLenFeature}$ objects.

Each VarlenFeature is mapped to a SparseTensor, and each FixedLenFeature is mapped to a Tensor.

Each VarLenFeature maps to a SparseTensor of the specified type representing a ragged matrix. Its indices are [batch,

index] where batch is the batch entry the value is from

in serialized, and index is the value's index in the list of values associated with that feature and example.

Each FixedLenFeature df maps to a Tensor of the specified type

(or tf.float32 if not specified) and shape (serialized.size(),) +

df.shape.

FixedLenFeature entries with a default_value are optional. With no default value, we will fail if thatFeature is missing from any example in serialized.

Examples:

For example, if one expects a tf.float32 sparse feature ft and three serialized Examples are provided:

```
serialized = [
  features
    { feature { key: "ft" value { float_list { value: [1.0,
2.0] } } },
  features
    { feature []},
  features
    { feature { key: "ft" value { float_list { value: [3.0] } } }
]
```

then the output will look like:

Given two Example input protos in serialized:

```
features {
  feature { key: "kw" value { bytes_list { value: [ "knit",
  "big" ] } }
  feature { key: "gps" value { float_list { value: [] } } }
},
  features {
  feature { key: "kw" value { bytes_list { value:
    ["emmy" ] } }
  feature { key: "dank" value { int64_list { value: [ 42 ] } } }
  feature { key: "gps" value { } }
}
```

And arguments

```
example_names: ["input0", "input1"],
features: {
    "kw": VarLenFeature(tf.string),
    "dank": VarLenFeature(tf.int64),
    "gps": VarLenFeature(tf.float),
}
```

Then the output is a dictionary:

```
"kw": SparseTensor(
    indices=[[0, 0], [0, 1], [1, 0]],
    values=["knit", "big", "emmy"]
    shape=[2, 2]),
"dank": SparseTensor(
    indices=[[1, 0]],
    values=[42],
    shape=[2, 1]),
"gps": SparseTensor(
    indices=[],
    values=[],
    shape=[2, 0]),
```

For dense results in two serialized Examples:

```
features {
  feature { key: "age" value { int64_list { value: [ 0 ] } } }
```

```
feature { key: "gender" value { bytes_list { value:
    ["f"] } }
},
features {
    feature { key: "age" value { int64_list { value: [] } } }
    feature { key: "gender" value { bytes_list { value:
    ["f"] } }
}
```

We can use arguments:

```
example_names: ["input0", "input1"],
features: {
    "age": FixedLenFeature([], dtype=tf.int64, default_value=-1),
    "gender": FixedLenFeature([], dtype=tf.string),
}
```

And the expected output is:

```
{
  "age": [[0], [-1]],
  "gender": [["f"], ["f"]],
}
```

Args:

- serialized: A vector (1-D Tensor) of strings, a batch of binary serialized Example protos.
- features: A dict mapping feature keys

to FixedLenFeature or VarLenFeature values.

- name: A name for this operation (optional).
- example_names: A vector (1-D Tensor) of strings (optional), the names of the serialized protos in the batch.

Returns:

A dict mapping feature keys to Tensor and SparseTensor values.

Raises:

ValueError: if any feature is invalid.

```
tf.parse_single_example(serialized, features, name=None,
example names=None)
```

Parses a single Example proto.

Similar to parse_example, except:

For dense tensors, the returned <code>Tensor</code> is identical to the output of <code>parse_example</code>, except there is no batch dimension, the output shape is the same as the shape given in <code>dense_shape</code>.

For SparseTensors, the first (batch) column of the indices matrix is removed (the indices matrix is a column vector), the values vector is unchanged, and the first (batch_size) entry of the shape vector is removed (it is now a single element vector).

Args:

- serialized: A scalar string Tensor, a single serialized Example.
 See parse single example rawdocumentation for more details.
- features: A dict mapping feature keys
 to FixedLenFeature or VarLenFeature values.
- name: A name for this operation (optional).

•	example_names: (Optional) A scalar string Tensor, the associated
	name. See_parse_single_example_raw documentation for more details.
	Returns:
	A dict mapping feature keys to Tensor and SparseTensor values.
	Raises:
•	ValueError: if any feature is invalid.
	tf.decode json example(json examples, name=None)
	Convert JSON-encoded Example records to binary protocol buffer strings.
	This op translates a tensor containing Example records, encoded using the <u>standard JSON mapping</u> , into a tensor containing the same records encoded as binary protocol buffers. The resulting tensor can then be fed to any of the other Example-parsing ops.
	Args:
•	json_examples: A Tensor of type string. Each string is a JSON object serialized according to the JSON mapping of the Example proto.
•	name: A name for the operation (optional).

Returns:

A Tensor of type string. Each string is a binary Example protocol buffer corresponding to the respective element of json examples.

Queues

TensorFlow provides several implementations of 'Queues', which are structures within the TensorFlow computation graph to stage pipelines of tensors together. The following describe the basic Queue interface and some implementations. To see an example use, see Threading and Queues.

class tf.QueueBase

Base class for queue implementations.

A queue is a TensorFlow data structure that stores tensors across multiple steps, and exposes operations that enqueue and dequeue tensors.

Each queue element is a tuple of one or more tensors, where each tuple component has a static dtype, and may have a static shape. The queue implementations support versions of enqueue and dequeue that handle single elements, versions that support enqueuing and dequeuing a batch of elements at once.

See tf.FIFOQueue and tf.RandomShuffleQueue for concrete implementations of this class, and instructions on how to create them.

tf.QueueBase.enqueue(vals, name=None)

Enqueues one element to this queue.

If the queue is full when this operation executes, it will block until the element has been enqueued.

Args:

- vals: The tuple of Tensor objects to be enqueued.
- name: A name for the operation (optional).

Returns:

The operation that enqueues a new tuple of tensors to the queue.

```
tf.QueueBase.enqueue many(vals, name=None)
```

Enqueues zero or elements to this queue.

This operation slices each component tensor along the 0th dimension to make multiple queue elements. All of the tensors in vals must have the same size in the 0th dimension.

If the queue is full when this operation executes, it will block until all of the elements have been enqueued.

Args:

- vals: The tensor or tuple of tensors from which the queue elements are taken.
- name: A name for the operation (optional).

Returns:

The operation that enqueues a batch of tuples of tensors to the queue.

```
tf.QueueBase.dequeue(name=None)
```

Dequeues one element from this queue.

If the queue is empty when this operation executes, it will block until there is an element to dequeue.

Args:

name: A name for the operation (optional).

Returns:

The tuple of tensors that was dequeued.

```
tf.QueueBase.dequeue many(n, name=None)
```

Dequeues and concatenates n elements from this queue.

This operation concatenates queue-element component tensors along the 0th dimension to make a single component tensor. All of the components in the dequeued tuple will have size n in the 0th dimension.

If the queue contains fewer than n elements when this operation executes, it will block until n elements have been dequeued.

Args:

- n: A scalar Tensor containing the number of elements to dequeue.
- name: A name for the operation (optional).

Returns:

The tuple of concatenated tensors that was dequeued.

```
tf.QueueBase.size(name=None)
```

Compute the number of elements in this queue.

Args:

name: A name for the operation (optional).

Returns:

A scalar tensor containing the number of elements in this queue.

```
tf.QueueBase.close(cancel_pending_enqueues=False,
name=None)
```

Closes this queue.

This operation signals that no more elements will be enqueued in the given queue. Subsequent enqueue andenqueue_many operations will fail. Subsequent dequeue and dequeue_many operations will continue to succeed if sufficient elements remain in the queue.

Subsequent dequeue and dequeue_many operations that would block will fail immediately.

If cancel_pending_enqueues is True, all pending requests will also be cancelled.

Args:

- cancel_pending_enqueues: (Optional.) A boolean, defaulting
 to False (described above).
- name: A name for the operation (optional).

Returns:

The operation that closes the queue.

Other Methods

```
tf.QueueBase. init (dtypes, shapes, queue ref)
```

Constructs a queue object from a queue reference.

Args:

- dtypes: A list of types. The length of dtypes must equal the number of tensors in each element.
- shapes: Constraints on the shapes of tensors in an element: A list of shape tuples or None. This list is the same length as dtypes. If the shape of any tensors in the element are constrained, all must be; shapes can be None if the shapes should not be constrained.

4	of OuguePage dtypes
	tf.QueueBase.dtypes
_	The list of dtypes for each component of a queue element.
+	tf.QueueBase.from list(index, queues)
	Create a queue using the queue reference from queues [index].
,	Args:
	index: An integer scalar tensor that determines the input that gets selected.
	queues: A list of QueueBase objects.
F	Returns:
,	A QueueBase object.
F	Raises:
Γ.	TypeError: When queues is not a list of QueueBase objects, or when
1	the data types of queues are not all the same.

```
tf.QueueBase.name
```

The name of the underlying queue.

```
tf.QueueBase.queue ref
```

The underlying queue reference.

```
class tf.FIFOQueue
```

A queue implementation that dequeues elements in first-in-first out order.

See tf.QueueBase for a description of the methods on this class.

```
tf.FIFOQueue.__init__(capacity, dtypes, shapes=None,
shared name=None, name='fifo queue')
```

Creates a queue that dequeues elements in a first-in first-out order.

A FIFOQueue has bounded capacity; supports multiple concurrent producers and consumers; and provides exactly-once delivery.

A FIFOQueue holds a list of up to capacity elements. Each element is a fixed-length tuple of tensors whose dtypes are described by dtypes, and whose shapes are optionally described by the shapes argument.

If the shapes argument is specified, each component of a queue element must have the respective fixed shape. If it is unspecified, different queue elements may have different shapes, but the use of dequeue many is disallowed.

Args:

- capacity: An integer. The upper bound on the number of elements that may be stored in this queue.
- dtypes: A list of DType objects. The length of dtypes must equal the number of tensors in each queue element.
- shapes: (Optional.) A list of fully-defined TensorShape objects, with the same length as dtypes or None.
- shared_name: (Optional.) If non-empty, this queue will be shared under the given name across multiple sessions.
- name: Optional name for the queue operation.

```
class tf.RandomShuffleOueue
```

A queue implementation that dequeues elements in a random order.

See tf.QueueBase for a description of the methods on this class.

```
tf.RandomShuffleQueue.__init__(capacity,
min_after_dequeue, dtypes, shapes=None, seed=None,
shared name=None, name='random shuffle queue')
```

Create a queue that dequeues elements in a random order.

A RandomShuffleQueue has bounded capacity; supports multiple concurrent producers and consumers; and provides exactly-once delivery.

A RandomShuffleQueue holds a list of up to capacity elements. Each element is a fixed-length tuple of tensors whose dtypes are described by dtypes, and whose shapes are optionally described by the shapesargument.

If the shapes argument is specified, each component of a queue element must have the respective fixed shape. If it is unspecified, different queue elements may have different shapes, but the use of dequeue many is disallowed.

The min_after_dequeue argument allows the caller to specify a minimum number of elements that will remain in the queue after a dequeue or dequeue_many operation completes, to ensure a minimum level of mixing of elements. This invariant is maintained by blocking those operations until sufficient elements have been enqueued. The min_after_dequeue argument is ignored after the queue has been closed.

Args:

- capacity: An integer. The upper bound on the number of elements
 that may be stored in this queue.
- min_after_dequeue: An integer (described above).
- dtypes: A list of DType objects. The length of dtypes must equal the number of tensors in each queue element.
- shapes: (Optional.) A list of fully-defined TensorShape objects, with the same length as dtypes or None.

• seed: A Python integer. Used to create a random seed.

See set random seed for behavior.

- shared_name: (Optional.) If non-empty, this queue will be shared under the given name across multiple sessions.
- name: Optional name for the queue operation.

Dealing with the filesystem

```
tf.matching files(pattern, name=None)
```

Returns the set of files matching a pattern.

Note that this routine only supports wildcard characters in the basename portion of the pattern, not in the directory portion.

Args:

- pattern: A Tensor of type string. A (scalar) shell wildcard pattern.
- name: A name for the operation (optional).

Returns:

A Tensor of type string. A vector of matching filenames.

```
tf.read file(filename, name=None)
```

Reads and outputs the entire contents of the input filename.

Args:

- filename: A Tensor of type string.
- name: A name for the operation (optional).

Returns:

A Tensor of type string.

Input pipeline

TensorFlow functions for setting up an input-prefetching pipeline. Please see the reading data how-to for context.

Beginning of an input pipeline

The "producer" functions add a queue to the graph and a corresponding <code>QueueRunner</code> for running the subgraph that fills that queue.

```
tf.train.match_filenames_once(pattern, name=None)
```

Save the list of files matching pattern, so it is only computed once.

Args:

• pattern: A file pattern (glob).

•	name: A name for the operations (optional).
	Returns:
	A variable that is initialized to the list of files matching pattern.
	tf.train.limit_epochs(tensor, num_epochs=None, name=None)
	Returns tensor num_epochs times and then raises
	an OutOfRange error.
	Args:
•	tensor: Any Tensor.
•	num_epochs: A positive integer (optional). If specified, limits the
	number of steps the output tensor may be evaluated.
•	name: A name for the operations (optional).
	Returns:
	tensor or OutOfRange.
	Raises:
•	ValueError: if num_epochs is invalid.

tf.train.range_input_producer(limit, num_epochs=None,
shuffle=True, seed=None, capacity=32, name=None)

Produces the integers from 0 to limit-1 in a queue.

Args:

- limit: An int32 scalar tensor.
- num_epochs: An integer (optional). If
 specified, range_input_producer produces each
 integernum_epochs times before generating an OutOfRange error. If
 not specified, range_input_producer can cycle through the integers an unlimited number of times.
- shuffle: Boolean. If true, the integers are randomly shuffled within each epoch.
- seed: An integer (optional). Seed used if shuffle == True.
- capacity: An integer. Sets the queue capacity.
- name: A name for the operations (optional).

Returns:

A Queue with the output integers. A QueueRunner for the Queue is added to the current Graph's QUEUE RUNNER collection.

tf.train.slice_input_producer(tensor_list,
num_epochs=None, shuffle=True, seed=None, capacity=32,
name=None)

Produces a slice of each Tensor in tensor_list.

Implemented using a Queue -- a QueueRunner for the Queue is added to the current Graph's QUEUE_RUNNER collection.

Args:

- tensor list: A list of Tensor objects.
 - Every Tensor in tensor_list must have the same size in the first dimension.
- num_epochs: An integer (optional). If
 specified, slice_input_producer produces each
 slicenum_epochs times before generating an OutOfRange error. If not
 specified, slice_input_producercan cycle through the slices an unlimited number of times.
- shuffle: Boolean. If true, the integers are randomly shuffled within each epoch.
- seed: An integer (optional). Seed used if shuffle == True.
- capacity: An integer. Sets the queue capacity.
- name: A name for the operations (optional).

Returns:

A list of tensors, one for each element of tensor_list. If the tensor in tensor_list has shape [N, a, b, ..., z], then the corresponding output tensor will have shape [a, b, ..., z].

Raises:

ValueError: if slice_input_producer produces nothingfrom tensor list.

```
tf.train.string_input_producer(string_tensor,
num_epochs=None, shuffle=True, seed=None, capacity=32,
name=None)
```

Output strings (e.g. filenames) to a queue for an input pipeline.

Args:

- string tensor: A 1-D string tensor with the strings to produce.
- num_epochs: An integer (optional). If
 specified, string_input_producer produces each string
 fromstring_tensor num_epochs times before generating an
 OutOfRange error. If not specified, string_input_producer can
 cycle through the strings in string_tensor an unlimited number of times.
- shuffle: Boolean. If true, the strings are randomly shuffled within each epoch.
- seed: An integer (optional). Seed used if shuffle == True.
- capacity: An integer. Sets the queue capacity.
- name: A name for the operations (optional).

Returns:

A queue with the output strings. A QueueRunner for the Queue is added to the current Graph's QUEUE RUNNER collection.

Raises:

 ValueError: If the string_tensor is a null Python list. At runtime, will fail with an assertion if string_tensor becomes a null tensor.

Batching at the end of an input pipeline

These functions add a queue to the graph to assemble a batch of examples, with possible shuffling. They also add a QueueRunner for running the subgraph that fills that queue.

Use batch or batch join for batching examples that have already

been well shuffled. Use shuffle_batch_join for examples that would benefit from additional shuffling.

Use batch or shuffle_batch if you want a single thread producing examples to batch, or if you have a single subgraph producing examples but you want to run it in N threads (where you increase N until it can keep the queue full).

Use batch_join or shuffle_batch_join if you have N different subgraphs producing examples to batch and you want them run by N threads.

tf.train.batch(tensor_list, batch_size, num_threads=1,
capacity=32, enqueue many=False, shapes=None, name=None)

Creates batches of tensors in tensor_list.

This function is implemented using a queue. A QueueRunner for the queue is added to the current Graph'sQUEUE_RUNNER collection.

If enqueue_many is False, tensor_list is assumed to represent a single example. An input tensor with shape [x, y, z] will be output as a tensor with shape [batch size, x, y, z].

If enqueue_many is True, tensor_list is assumed to represent a batch of examples, where the first dimension is indexed by example, and all members of tensor_list should have the same size in the first dimension. If an input tensor has shape [*, x, y, z], the output will have shape [batch_size, x, y, z].

The capacity argument controls the how long the prefetching is allowed to grow the queues.

The returned operation is a dequeue operation and will throw tf.errors.OutOfRangeError if the input queue is exhausted. If this operation is feeding another input queue, its queue runner will catch this exception, however, if this operation is used in your main thread you are responsible for catching this yourself.

N.B.: You must ensure that either (i) the shapes argument is passed, or (ii) all of the tensors in tensor_listmust have fully-defined shapes. ValueError will be raised if neither of these conditions holds.

Args:

- tensor list: The list of tensors to enqueue.
- batch_size: The new batch size pulled from the queue.
- num_threads: The number of threads enqueuing tensor_list.

- capacity: An integer. The maximum number of elements in the queue.
- enqueue_many: Whether each tensor in tensor_list is a single example.
- shapes: (Optional) The shapes for each example. Defaults to the inferred shapes for tensor list.
- name: (Optional) A name for the operations.

Returns:

A list of tensors with the same number and types as tensor list.

Raises:

 ValueError: If the shapes are not specified, and cannot be inferred from the elements of tensor list.

```
tf.train.batch_join(tensor_list_list, batch_size,
capacity=32, enqueue many=False, shapes=None, name=None)
```

Runs a list of tensors to fill a queue to create batches of examples.

Enqueues a different list of tensors in different threads. Implemented using a queue -- a QueueRunner for the queue is added to the

current Graph's QUEUE_RUNNER collection.

len(tensor list list) threads will be started, with

thread i enqueuing the tensors

from tensor_list_list[i]. tensor_list_list[i1][j] must match tensor_list_list[i2][j] in type and shape, except in the first dimension if enqueue many is true.

If enqueue_many is False, each tensor_list_list[i] is assumed to represent a single example. An input tensor x will be output as a tensor with shape [batch size] + x.shape.

If $enqueue_many$ is True, $tensor_list_list[i]$ is assumed to represent a batch of examples, where the first dimension is indexed by example, and all members of $tensor_list_list[i]$ should have the same size in the first dimension. The slices of any input tensor x are treated as examples, and the output tensors will have

shape [batch_size] + x.shape[1:].

The capacity argument controls the how long the prefetching is allowed to grow the queues.

The returned operation is a dequeue operation and will

throw tf.errors.OutOfRangeError if the input queue is exhausted.

If this operation is feeding another input queue, its queue runner will catch this exception, however, if this operation is used in your main thread you are responsible for catching this yourself.

N.B.: You must ensure that either (i) the shapes argument is passed, or (ii) all of the tensors intensor_list_list must have fully-defined shapes. ValueError will be raised if neither of these conditions holds.

Args:

• tensor_list_list: A list of tuples of tensors to enqueue.

- batch size: An integer. The new batch size pulled from the queue.
- capacity: An integer. The maximum number of elements in the queue.
- enqueue_many: Whether each tensor in tensor_list_list is a single example.
- shapes: (Optional) The shapes for each example. Defaults to the
 inferred shapes fortensor list list[i].
- name: (Optional) A name for the operations.

Returns:

A list of tensors with the same number and types as tensor list list[i].

Raises:

ValueError: If the shapes are not specified, and cannot be inferred
 from the elements oftensor list list.

```
tf.train.shuffle_batch(tensor_list, batch_size, capacity,
min_after_dequeue, num_threads=1, seed=None,
enqueue_many=False, shapes=None, name=None)
```

Creates batches by randomly shuffling tensors.

This function adds the following to the current Graph:

 A shuffling queue into which tensors from tensor_list are enqueued.

- A dequeue many operation to create batches from the queue.
- A QueueRunner to QUEUE_RUNNER collection, to enqueue the tensors
 from tensor list.

If enqueue_many is False, tensor_list is assumed to represent a single example. An input tensor with shape [x, y, z] will be output as a tensor with shape [batch size, x, y, z].

If enqueue_many is True, tensor_list is assumed to represent a batch of examples, where the first dimension is indexed by example, and all members of tensor_list should have the same size in the first dimension. If an input tensor has shape [*, x, y, z], the output will have shape [batch_size, x, y, z].

The capacity argument controls the how long the prefetching is allowed to grow the queues.

The returned operation is a dequeue operation and will

throw tf.errors.OutOfRangeError if the input queue is exhausted.

If this operation is feeding another input queue, its queue runner will catch this exception, however, if this operation is used in your main thread you are responsible for catching this yourself.

For example:

```
# Creates batches of 32 images and 32 labels.
image_batch, label_batch = tf.train.shuffle_batch(
    [single_image, single_label],
    batch_size=32,
    num_threads=4,
    capacity=50000,
    min_after_dequeue=10000)
```

N.B.: You must ensure that either (i) the shapes argument is passed, or (ii) all of the tensors in tensor_listmust have fully-defined

shapes. ValueError will be raised if neither of these conditions holds.

Args:

- tensor list: The list of tensors to enqueue.
- batch size: The new batch size pulled from the queue.
- capacity: An integer. The maximum number of elements in the queue.
- min_after_dequeue: Minimum number elements in the queue after a dequeue, used to ensure a level of mixing of elements.
- num threads: The number of threads enqueuing tensor list.
- seed: Seed for the random shuffling within the queue.
- enqueue_many: Whether each tensor in tensor_list is a single example.
- shapes: (Optional) The shapes for each example. Defaults to the inferred shapes for tensor_list.
- name: (Optional) A name for the operations.

Returns:

A list of tensors with the same number and types as tensor_list.

Raises:

 ValueError: If the shapes are not specified, and cannot be inferred from the elements of tensor_list.

```
tf.train.shuffle_batch_join(tensor_list_list, batch_size,
capacity, min_after_dequeue, seed=None,
enqueue_many=False, shapes=None, name=None)
```

Create batches by randomly shuffling tensors.

This version enqueues a different list of tensors in different threads. It adds the following to the current Graph:

- A shuffling queue into which tensors from tensor_list_list are enqueued.
- A dequeue many operation to create batches from the queue.
- A QueueRunner to QUEUE_RUNNER collection, to enqueue the tensors
 from tensor_list_list.

len(tensor_list_list) threads will be started, with

thread ${\scriptscriptstyle \perp}$ enqueuing the tensors

from tensor_list_list[i]. tensor_list_list[i1][j] must match tensor_list_list[i2][j] in type and shape, except in the first dimension if enqueue_many is true.

If enqueue_many is False, each tensor_list_list[i] is assumed to represent a single example. An input tensor with shape [x, y,

z] will be output as a tensor with shape [batch_size, x, y, z].

If enqueue_many is True, tensor_list_list[i] is assumed to represent a batch of examples, where the first dimension is indexed by example, and all members of tensor_list_list[i] should have

the same size in the first dimension. If an input tensor has shape [*,

```
x, y, z], the output will have shape [batch size, x, y, z].
```

The capacity argument controls the how long the prefetching is allowed to grow the queues.

The returned operation is a dequeue operation and will

throw tf.errors.OutOfRangeError if the input queue is exhausted.

If this operation is feeding another input queue, its queue runner will catch this exception, however, if this operation is used in your main thread you are responsible for catching this yourself.

Args:

- tensor list list: A list of tuples of tensors to enqueue.
- batch size: An integer. The new batch size pulled from the queue.
- capacity: An integer. The maximum number of elements in the queue.
- min_after_dequeue: Minimum number elements in the queue after a dequeue, used to ensure a level of mixing of elements.
- seed: Seed for the random shuffling within the queue.
- enqueue_many: Whether each tensor in tensor_list_list is a single example.
- shapes: (Optional) The shapes for each example. Defaults to the inferred shapes fortensor list list[i].
- name: (Optional) A name for the operations.

Returns:

A list of tensors with the same number and types as tensor list list[i].

Raises:

ValueError: If the shapes are not specified, and cannot be inferred
 from the elements oftensor list list.

Data IO (Python functions)

Contents

- Data IO (Python functions)
- Data IO (Python Functions)
- class tf.python_io.TFRecordWriter
- tf.python io.tf record iterator(path)
- TFRecords Format Details

Data IO (Python Functions)

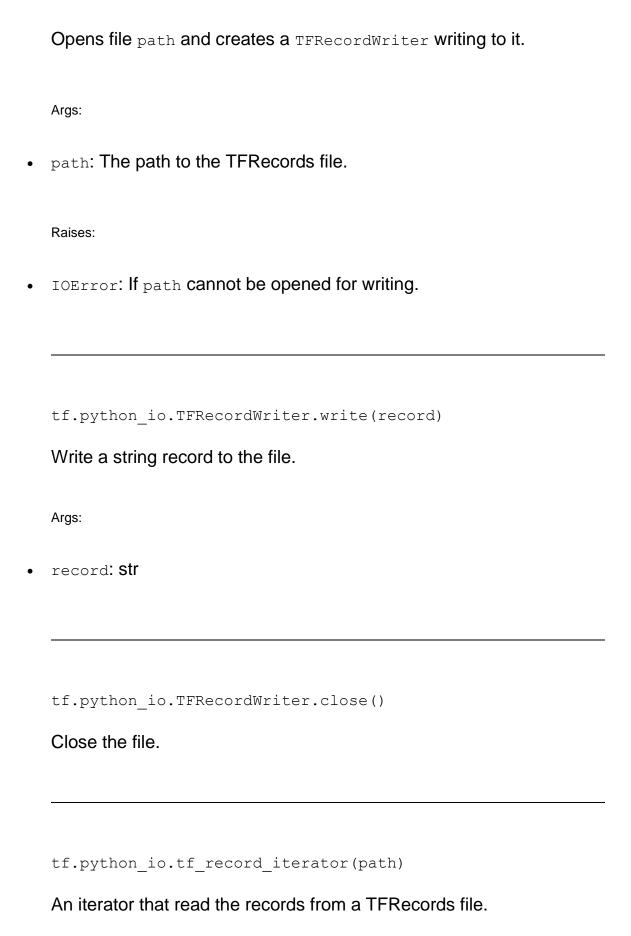

A TFRecords file represents a sequence of (binary) strings. The format is not random access, so it is suitable for streaming large amounts of data but not suitable if fast sharding or other non-sequential access is desired.

```
class tf.python io.TFRecordWriter
```

A class to write records to a TFRecords file.

This class implements __enter__ and __exit__, and can be used in with blocks like a normal file.

```
tf.python io.TFRecordWriter. init (path)
```

Args:

path: The path to the TFRecords file.

Yields:

Strings.

Raises:

• IOError: If path cannot be opened for reading.

TFRecords Format Details

A TFRecords file contains a sequence of strings with CRC hashes. Each record has the format

```
uint64 length
uint32 masked_crc32_of_length
byte data[length]
uint32 masked_crc32_of_data
```

and the records are concatenated together to produce the file. The CRC32s are described here, and the mask of a CRC is

```
masked crc = ((crc >> 15) | (crc << 17)) + 0xa282ead8ul
```

Activation Functions

The activation ops provide different types of nonlinearities for use in neural networks. These include smooth nonlinearities

(sigmoid, tanh, elu, softplus, and softsign), continuous but not

everywhere differentiable functions (relu, relu6, and relu_x), and random regularization (dropout).

All activation ops apply componentwise, and produce a tensor of the same shape as the input tensor.

```
tf.nn.relu(features, name=None)
  Computes rectified linear: max(features, 0).
   Args:
 features: A Tensor. Must be one of the following
  types: float32, float64, int32, int64, uint8, int16, int8, uint16.
• name: A name for the operation (optional).
   Returns:
  A Tensor. Has the same type as features.
   tf.nn.relu6(features, name=None)
   Computes Rectified Linear 6: min (max (features, 0), 6).
   Args:
 features: A Tensor with
  type float, double, int32, int64, uint8, int16, or int8.
• name: A name for the operation (optional).
   Returns:
```

```
tf.nn.elu(features, name=None)
```

A Tensor with the same type as features.

Computes exponential linear: exp(features) - 1 if <

0, features otherwise.

See <u>Fast and Accurate Deep Network Learning by Exponential</u> Linear Units (ELUs)

Args:

features: A Tensor. Must be one of the following

types: float32, float64.

• name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as features.

```
tf.nn.softplus(features, name=None)
```

Computes softplus: log(exp(features) + 1).

Args:

features: A Tensor. Must be one of the following types: float32, float64, int32, int64, uint8, int16, int8, uint16. name: A name for the operation (optional). Returns: A Tensor. Has the same type as features. tf.nn.softsign(features, name=None) Computes softsign: features / (abs(features) + 1). Args: • features: A Tensor. Must be one of the following types: float32, float64, int32, int64, uint8, int16, int8, uint16. name: A name for the operation (optional). Returns: A Tensor. Has the same type as features.

tf.nn.dropout(x, keep_prob, noise_shape=None, seed=None,
name=None)

Computes dropout.

With probability $keep_prob$, outputs the input element scaled up by 1 / $keep_prob$, otherwise outputs 0. The scaling is so that the expected sum is unchanged. By default, each element is kept or dropped independently. If $noise_shape$ is specified, it must be broadcastable to the shape of x, and only dimensions with $noise_shape[i] == shape(x)[i]$ will make independent decisions. For example, if shape(x) = [k, l, m, l] and $noise_shape = [k, l, l, l]$, each batch and channel component will be kept independently and each row and column will be kept or not kept together.

Args:

- x: A tensor.
- keep_prob: A scalar Tensor with the same type as x. The probability that each element is kept.
- noise_shape: A 1-D Tensor of type int32, representing the shape for randomly generated keep/drop flags.
- seed: A Python integer. Used to create random seeds.

See set_random_seed for behavior.

name: A name for this operation (optional).

Returns:

A Tensor of the same shape of x.

Raises:

• ValueError: If keep prob is not in (0, 1].

```
tf.nn.bias_add(value, bias, name=None)
Adds bias to value.
```

This is (mostly) a special case of tf.add where bias is restricted to 1-D. Broadcasting is supported, so valuemay have any number of dimensions. Unlike tf.add, the type of bias is allowed to differ from value in the case where both types are quantized.

Args:

- value: A Tensor with
 type float, double, int64, int32, uint8, int16, int8, or complex64.
- bias: A 1-D Tensor with size matching the last dimension of value.
 Must be the same type as valueunless value is a quantized type, in which case a different quantized type may be used.
- name: A name for the operation (optional).

Returns:

A Tensor with the same type as value.

Computes sigmoid of $\ensuremath{\mathrm{x}}$ element-wise.

```
Specifically, y = 1 / (1 + exp(-x)).
```

Args:

- x: A Tensor with type float, double, int32, complex64, int64,
 or qint32.
- name: A name for the operation (optional).

Returns:

A Tensor with the same type as x if x.dtype != qint32 otherwise the return type is quint8.

```
tf.tanh(x, name=None)
```

Computes hyperbolic tangent of \mathbf{x} element-wise.

Args:

- x: A Tensor with type float, double, int32, complex64, int64,
 or qint32.
- name: A name for the operation (optional).

Returns:

A Tensor with the same type as x if x.dtype != qint32 otherwise the return type is quint8.

Convolution

The convolution ops sweep a 2-D filter over a batch of images, applying the filter to each window of each image of the appropriate size. The different ops trade off between generic vs. specific filters:

- conv2d: Arbitrary filters that can mix channels together.
- depthwise_conv2d: Filters that operate on each channel independently.
- separable_conv2d: A depthwise spatial filter followed by a pointwise filter.

Note that although these ops are called "convolution", they are strictly speaking "cross-correlation" since the filter is combined with an input window without reversing the filter. For details, see the properties of cross-correlation.

The filter is applied to image patches of the same size as the filter and strided according to the strides argument. strides = [1, 1,

- 1, 1] applies the filter to a patch at every offset, strides = [1, 2,
- 2, 1] applies the filter to every other image patch in each dimension, etc.

Ignoring channels for the moment, and assume that the 4-

D input has shape [batch, in_height, in_width, ...] and the

4-D filter has shape [filter_height, filter_width, ...],

then the spatial semantics of the convolution ops are as follows: first, according to the padding scheme chosen as <code>'SAME'OR'VALID'</code>, the output size and the padding pixels are computed. For

the 'SAME' padding, the output height and width are computed as:

```
out height = ceil(float(in height) / float(strides[1]))
```

```
out_width = ceil(float(in_width) / float(strides[2]))
```

and the padding on the top and left are computed as:

Note that the division by 2 means that there might be cases when the padding on both sides (top vs bottom, right vs left) are off by one. In this case, the bottom and right sides always get the one additional

padded pixel. For example, when pad along height is 5, we pad 2

pixels at the top and 3 pixels at the bottom. Note that this is different from existing libraries such as cuDNN and Caffe, which explicitly specify the number of padded pixels and always pad the same number of pixels on both sides.

For the 'VALID' padding, the output height and width are computed as:

```
out_height = ceil(float(in_height - filter_height + 1) /
float(strides[1]))
out_width = ceil(float(in_width - filter_width + 1) /
float(strides[2]))
```

and the padding values are always zero. The output is then computed as

where any value outside the original input image region are considered zero (i.e. we pad zero values around the border of the image).

Since input is 4-D, each input[b, i, j, :] is a vector.

For conv2d, these vectors are multiplied by the filter [di,

dj, :, :] matrices to produce new vectors.

For depthwise_conv_2d, each scalar component input[b, i, j, k] is multiplied by a vector filter[di, dj, k], and all the vectors are concatenated.

```
tf.nn.conv2d(input, filter, strides, padding,
use_cudnn_on_gpu=None, name=None)
```

Computes a 2-D convolution given 4-D input and filter tensors.

Given an input tensor of shape [batch, in_height, in_width, in_channels] and a filter / kernel tensor of shape [filter_height, filter_width, in_channels, out_channels], this op performs the following:

- 1. Flattens the filter to a 2-D matrix with shape [filter_height *
 filter width * in channels, output channels].
- 2. Extracts image patches from the input tensor to form a virtual tensor of shape [batch, out_height, out_width, filter_height * filter width * in channels].
- 3. For each patch, right-multiplies the filter matrix and the image patch vector.

In detail,

```
output[b, i, j, k] =
    sum_{di, dj, q} input[b, strides[1] * i + di, strides[2] * j +
dj, q] *
    filter[di, dj, q, k]
```

Must have strides[0] = strides[3] = 1. For the most common case of the same horizontal and vertices strides, strides = [1, stride, stride, 1].

Args:

- input: A Tensor. Must be one of the following
 types: float32, float64.
- filter: A Tensor. Must have the same type as input.
- strides: A list of ints. 1-D of length 4. The stride of the sliding window for each dimension of input.
- padding: A string from: "SAME", "VALID". The type of padding algorithm to use.
- use_cudnn_on_gpu: An optional bool. Defaults to True.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input.

tf.nn.depthwise_conv2d(input, filter, strides, padding,
name=None)

Depthwise 2-D convolution.

Given an input tensor of shape [batch, in_height, in_width, in_channels] and a filter tensor of shape [filter_height, filter_width, in_channels, channel_multiplier] containingin_channels convolutional filters of depth 1, depthwise_conv2d applies a different filter to each input channel (expanding from 1 channel

to channel_multiplier channels for each), then concatenates the results together. The output has in_channels * channel_multiplier channels.

In detail,

```
output[b, i, j, k * channel_multiplier + q] =
   sum_{di, dj} input[b, strides[1] * i + di, strides[2] * j +
dj, k] *
   filter[di, dj, k, q]
```

Must have strides[0] = strides[3] = 1. For the most common case of the same horizontal and vertical strides, strides = [1, stride, stride, 1].

Args:

- input: 4-D with shape [batch, in_height, in_width, in channels].
- filter: 4-D with shape [filter_height, filter_width, in_channels, channel_multiplier].
- strides: 1-D of size 4. The stride of the sliding window for each dimension of input.
- padding: A string, either 'VALID' or 'SAME'. The padding algorithm.
- name: A name for this operation (optional).

Returns:

```
A 4-D Tensor of shape [batch, out_height, out_width, in channels * channel multiplier].
```

```
tf.nn.separable_conv2d(input, depthwise_filter,
pointwise filter, strides, padding, name=None)
```

2-D convolution with separable filters.

Performs a depthwise convolution that acts separately on channels followed by a pointwise convolution that mixes channels. Note that this is separability between dimensions [1, 2] and 3, not spatial separability between dimensions 1 and 2.

In detail,

```
output[b, i, j, k] = sum_{di, dj, q, r]
input[b, strides[1] * i + di, strides[2] * j + dj, q] *
depthwise_filter[di, dj, q, r] *
pointwise_filter[0, 0, q * channel_multiplier + r, k]
```

strides controls the strides for the depthwise convolution only, since the pointwise convolution has implicit strides of [1, 1, 1, 1]. Must have strides[0] = strides[3] = 1. For the most common case of the same horizontal and vertical strides, strides = [1, stride, stride, 1].

Args:

input: 4-D Tensor with shape [batch, in_height, in_width, in channels].

- depthwise_filter: 4-D Tensor with shape [filter_height, filter_width, in_channels, channel_multiplier].
 Contains in channels convolutional filters of depth 1.
- pointwise_filter: 4-D Tensor with shape [1, 1, channel_multiplier * in_channels, out_channels]. Pointwise filter to mix channels after depthwise_filter has convolved spatially.
- strides: 1-D of size 4. The strides for the depthwise convolution for each dimension of input.
- padding: A string, either 'VALID' or 'SAME'. The padding algorithm.
- name: A name for this operation (optional).

Returns:

A 4-D Tensor of shape [batch, out_height, out_width, out_channels].

tf.nn.conv2d_transpose(value, filter, output_shape,
strides, padding='SAME', name=None)

The transpose of conv2d.

This operation is sometimes called "deconvolution" after (Deconvolutional Networks)[http://www.matthewzeiler.com/pubs/cvpr2010/cvpr2010.pd

f], but is actually the transpose (gradient) of conv2drather than an actual deconvolution.

Args:

- value: A 4-D Tensor of type float and shape [batch, height, width, in channels].
- filter: A 4-D Tensor with the same type as value and shape [height, width, output_channels, in_channels]. filter's in_channels dimension must match that of value.
- output_shape: A 1-D Tensor representing the output shape of the deconvolution op.
- strides: A list of ints. The stride of the sliding window for each dimension of the input tensor.
- padding: A string, either 'VALID' or 'SAME'. The padding algorithm.
- name: Optional name for the returned tensor.

Returns:

A Tensor with the same type as value.

Raises:

ValueError: If input/output depth does not match filter's shape, or
 if padding is other than 'VALID' or'SAME'.

Pooling

The pooling ops sweep a rectangular window over the input tensor, computing a reduction operation for each window (average, max, or

max with argmax). Each pooling op uses rectangular windows of size ksize separated by offset strides. For example, if strides is all ones every window is used, if strides is all twos every other window is used in each dimension, etc.

In detail, the output is

```
output[i] = reduce(value[strides * i:strides * i + ksize])
where the indices also take into consideration the padding values.
Please refer to the Convolution section for details about the padding calculation.
```

```
tf.nn.avg pool(value, ksize, strides, padding, name=None)
```

Performs the average pooling on the input.

Each entry in output is the mean of the corresponding size ksize window in value.

Args:

- value: A 4-D Tensor of shape [batch, height, width, channels] and type float32, float64, qint8, quint8, or qint32.
- ksize: A list of ints that has length >= 4. The size of the window for each dimension of the input tensor.
- strides: A list of ints that has length >= 4. The stride of the sliding window for each dimension of the input tensor.
- padding: A string, either 'VALID' or 'SAME'. The padding algorithm.
- name: Optional name for the operation.

Returns:

A Tensor with the same type as value. The average pooled output tensor.

tf.nn.max pool(value, ksize, strides, padding, name=None)

Performs the max pooling on the input.

Args:

- value: A 4-D Tensor with shape [batch, height, width, channels] and type tf.float32.
- ksize: A list of ints that has length >= 4. The size of the window for each dimension of the input tensor.
- strides: A list of ints that has length >= 4. The stride of the sliding window for each dimension of the input tensor.
- padding: A string, either 'VALID' or 'SAME'. The padding algorithm.
- name: Optional name for the operation.

Returns:

A Tensor with type tf.float32. The max pooled output tensor.

tf.nn.max_pool_with_argmax(input, ksize, strides,
padding, Targmax=None, name=None)

Performs max pooling on the input and outputs both max values and indices.

The indices in argmax are flattened, so that a maximum value at position [b, y, x, c] becomes flattened index ((b * height + y) * width + x) * channels + c.

Args:

- input: A Tensor of type float32. 4-D with shape [batch, height, width, channels]. Input to pool over.
- ksize: A list of ints that has length >= 4. The size of the window for each dimension of the input tensor.
- strides: A list of ints that has length >= 4. The stride of the sliding window for each dimension of the input tensor.
- padding: A string from: "SAME", "VALID". The type of padding algorithm to use.
- Targmax: An optional tf.DType from: tf.int32, tf.int64. Defaults to tf.int64.
- name: A name for the operation (optional).

Returns:

A tuple of Tensor objects (output, argmax).

- output: A Tensor of type float32. The max pooled output tensor.
- argmax: A Tensor of type Targmax. 4-D. The flattened indices of the max values chosen for each output.

Normalization

Normalization is useful to prevent neurons from saturating when inputs may have varying scale, and to aid generalization.

```
tf.nn.12 normalize(x, dim, epsilon=1e-12, name=None)
```

Normalizes along dimension dim using an L2 norm.

```
For a 1-D tensor with dim = 0, computes
```

```
output = x / sqrt(max(sum(x**2), epsilon))
```

For x with more dimensions, independently normalizes each 1-D slice along dimension dim.

Args:

- x: A Tensor.
- dim: Dimension along which to normalize.
- epsilon: A lower bound value for the norm. Will
 use sqrt (epsilon) as the divisor if norm < sqrt (epsilon).
- name: A name for this operation (optional).

Returns:

A Tensor with the same shape as x.

```
tf.nn.local_response_normalization(input,
depth_radius=None, bias=None, alpha=None, beta=None,
name=None)
```

Local Response Normalization.

The 4-D input tensor is treated as a 3-D array of 1-D vectors (along the last dimension), and each vector is normalized independently. Within a given vector, each component is divided by the weighted, squared sum of inputs within depth radius. In detail,

```
sqr_sum[a, b, c, d] =
   sum(input[a, b, c, d - depth_radius : d + depth_radius + 1] **
2)
output = input / (bias + alpha * sqr_sum ** beta)
For details, see Krizhevsky et al., ImageNet classification with deep
```

For details, see Krizhevsky et al., ImageNet classification with deep convolutional neural networks (NIPS 2012).

Args:

- input: A Tensor of type float32. 4-D.
- depth_radius: An optional int. Defaults to 5. 0-D. Half-width of the
 1-D normalization window.
- bias: An optional float. Defaults to 1. An offset (usually positive to avoid dividing by 0).
- alpha: An optional float. Defaults to 1. A scale factor, usually positive.
- beta: An optional float. Defaults to 0.5. An exponent.
- name: A name for the operation (optional).

Returns:

A Tensor of type float32.

```
tf.nn.moments(x, axes, name=None, keep_dims=False)
```

Calculate the mean and variance of x.

The mean and variance are calculated by aggregating the contents of x across axes. If x is 1-D and axes = [0] this is just the mean and variance of a vector.

For so-called "global normalization" needed for convolutional filters pass axes=[0, 1, 2] (batch, height, width). For batch normalization pass axes=[0] (batch).

Args:

- x: A Tensor.
- axes: array of ints. Axes along which to compute mean and variance.
- keep_dims: produce moments with the same dimensionality as the input.
- name: Name used to scope the operations that compute the moments.

Returns:

Two Tensor objects: mean and variance.

Losses

The loss ops measure error between two tensors, or between a tensor and zero. These can be used for measuring accuracy of a network in a regression task or for regularization purposes (weight decay).

```
tf.nn.12 loss(t, name=None)
```

L2 Loss.

Computes half the L2 norm of a tensor without the sqrt:

```
output = sum(t ** 2) / 2
```

Args:

• t: A Tensor. Must be one of the following

types: float32, float64, int64, int32, uint8, uint16, int16, int8, complex64, qint8, quint8, qint32. Typically 2-D, but may have any dimensions.

name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as t. 0-D.

Classification

TensorFlow provides several operations that help you perform classification.

```
tf.nn.sigmoid_cross_entropy_with_logits(logits, targets,
name=None)
```

Computes sigmoid cross entropy given logits.

Measures the probability error in discrete classification tasks in which each class is independent and not mutually exclusive. For instance, one could perform multilabel classification where a picture can contain both an elephant and a dog at the same time.

For brevity, let x = logits, z = targets. The logistic loss is

```
 \begin{array}{l} z \ * \ -log(sigmoid(x)) \ + \ (1 \ - \ z) \ * \ -log(1 \ - \ sigmoid(x)) \\ = z \ * \ -log(1 \ / \ (1 \ + \ exp(-x))) \ + \ (1 \ - \ z) \ * \ -log(exp(-x) \ / \ (1 \ + \ exp(-x))) \\ = z \ * \ log(1 \ + \ exp(-x)) \ + \ (1 \ - \ z) \ * \ (-log(exp(-x)) \ + \ log(1 \ + \ exp(-x))) \\ = z \ * \ log(1 \ + \ exp(-x)) \ + \ (1 \ - \ z) \ * \ (x \ + \ log(1 \ + \ exp(-x))) \\ = (1 \ - \ z) \ * \ x \ + \ log(1 \ + \ exp(-x)) \\ = x \ - x \ * \ z \ + \ log(1 \ + \ exp(-x)) \end{array}
```

To ensure stability and avoid overflow, the implementation uses

```
\max(x, 0) - x * z + \log(1 + \exp(-abs(x)))
```

logits and targets must have the same type and shape.

Args:

- logits: A Tensor of type float32 or float64.
- targets: A Tensor of the same type and shape as logits.
- name: A name for the operation (optional).

Returns:

A Tensor of the same shape as logits with the componentwise logistic losses.

Computes softmax activations.

For each batch i and class j we have

```
softmax[i, j] = exp(logits[i, j]) / sum(exp(logits[i]))
```

Args:

logits: A Tensor. Must be one of the following

```
types: float32, float64. 2-D with shape[batch_size,
num_classes].
```

name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as logits. Same shape as logits.

```
tf.nn.softmax_cross_entropy_with_logits(logits, labels,
name=None)
```

Computes softmax cross entropy between logits and labels.

Measures the probability error in discrete classification tasks in which the classes are mutually exclusive (each entry is in exactly one class). For example, each CIFAR-10 image is labeled with one and only one label: an image can be a dog or a truck, but not both.

NOTE:: While the classes are mutually exclusive, their probabilities need not be. All that is required is that each row of labels is a valid probability distribution. If using exclusive labels (wherein one and

only one class is true at a time),

See sparse softmax cross entropy with logits.

WARNING: This op expects unscaled logits, since it performs a softmax on logits internally for efficiency. Do not call this op with the output of softmax, as it will produce incorrect results.

logits and labels must have the same shape [batch_size, num classes] and the same dtype (eitherfloat32 or float64).

Args:

- logits: Unscaled log probabilities.
- labels: Each row labels[i] must be a valid probability distribution.
- name: A name for the operation (optional).

Returns:

A 1-D Tensor of length batch_size of the same type as logits with the softmax cross entropy loss.

```
tf.nn.sparse_softmax_cross_entropy_with_logits(logits,
labels, name=None)
```

Computes sparse softmax cross entropy

between logits and labels.

Measures the probability error in discrete classification tasks in which the classes are mutually exclusive (each entry is in exactly one class). For example, each CIFAR-10 image is labeled with one and only one label: an image can be a dog or a truck, but not both. NOTE:: For this operation, the probability of a given label is considered exclusive. That is, soft classes are not allowed, and the labels vector must provide a single specific index for the true class for each row of logits(each minibatch entry). For soft softmax

classification with a probability distribution for each entry,

```
Seesoftmax_cross_entropy_with_logits.
```

WARNING: This op expects unscaled logits, since it performs a softmax on logits internally for efficiency. Do not call this op with the output of softmax, as it will produce incorrect results.

logits and must have the shape [batch_size, num_classes] and the dtype (either float32 orfloat64).

labels must have the shape [batch size] and the dtype int64.

Args:

- logits: Unscaled log probabilities.
- labels: Each entry labels[i] must be an index in [0, num classes).
- name: A name for the operation (optional).

Returns:

A 1-D Tensor of length batch_size of the same type as logits with the softmax cross entropy loss.

Embeddings

TensorFlow provides library support for looking up values in embedding tensors.

```
tf.nn.embedding_lookup(params, ids,
partition_strategy='mod', name=None,
validate indices=True)
```

Looks up ids in a list of embedding tensors.

This function is used to perform parallel lookups on the list of tensors in params. It is a generalization of tf.gather(), where params is interpreted as a partition of a larger embedding tensor.

If len (params) > 1, each element id of ids is partitioned between the elements of params according to the partition_strategy. In all strategies, if the id space does not evenly divide the number of partitions, each of the first (max_id + 1) % len(params) partitions will be assigned one more id.

If partition_strategy is "mod", we assign each id to partition p = id % len(params). For instance, 13 ids are split across 5 partitions as: [[0, 5, 10], [1, 6, 11], [2, 7, 12], [3, 8], [4, 9]]

If partition_strategy is "div", we assign ids to partitions in a contiguous manner. In this case, 13 ids are split across 5 partitions as: [[0, 1, 2], [3, 4, 5], [6, 7, 8], [9, 10], [11, 12]]

The results of the lookup are concatenated into a dense tensor. The returned tensor has shape shape (ids) + shape (params) [1:].

Args:

- params: A list of tensors with the same type and which can be concatenated along dimension 0. EachTensor must be appropriately sized for the given partition_strategy.
- ids: A Tensor with type int32 or int64 containing the ids to be looked up in params.
- partition_strategy: A string specifying the partitioning strategy,
 relevant if len(params) > 1. Currently "div" and "mod" are
 supported. Default is "mod".
- name: A name for the operation (optional).
- validate indices: Whether or not to validate gather indices.

Returns:

A Tensor with the same type as the tensors in params.

Raises:

• ValueError: If params is empty.

Evaluation

The evaluation ops are useful for measuring the performance of a network. Since they are nondifferentiable, they are typically used at evaluation time.

```
tf.nn.top k(input, k=1, sorted=True, name=None)
```

Finds values and indices of the $\ensuremath{\Bbbk}$ largest entries for the last dimension.

If the input is a vector (rank-1), finds the k largest entries in the vector and outputs their values and indices as vectors. Thus values[j] is the j-th largest entry in input, and its index is indices[j].

For matrices (resp. higher rank input), computes the top $\mbox{$k$}$ entries in each row (resp. vector along the last dimension). Thus,

```
values.shape = indices.shape = input.shape[:-1] + [k]
```

If two elements are equal, the lower-index element appears first.

Args:

- input: 1-D or higher Tensor with last dimension at least k.
- k: 0-D int32 Tensor. Number of top elements to look for along the last dimension (along each row for matrices).
- sorted: If true the resulting k elements will be sorted by the values in descending order.
- name: Optional name for the operation.

Returns:

- values: The k largest elements along each last dimensional slice.
- indices: The indices of values within the last dimension of input.

Says whether the targets are in the top K predictions.

This outputs a batch_size bool array, an entry out[i] is true if the prediction for the target class is among the top k predictions among all predictions for example i. Note that the behavior of InTopk differs from the Topkop in its handling of ties; if multiple classes have the same prediction value and straddle the top-k boundary, all of those classes are considered to be in the top k.

More formally, let

predictionsipredictionsi be the predictions for all classes for example i, targetsitargetsi be the target class for example i, outlout be the output for example i,

 $out_i \!\!=\!\! predictions_{i,targets_i} \!\! \in \!\!$

TopKIncludingTies(predictionsi)outi=predictionsi, targetsi∈TopKInclud
ingTies(predictionsi)

Args:

- predictions: A Tensor of type float32.
 A batch size X classes tensor.
- targets: A Tensor. Must be one of the following types: int32, int64.
 A batch_size vector of class ids.
- k: An int. Number of top elements to look at for computing precision.
- name: A name for the operation (optional).

Returns:

A Tensor of type bool. Computed Precision at k as a bool Tensor.

Candidate Sampling

Do you want to train a multiclass or multilabel model with thousands or millions of output classes (for example, a language model with a large vocabulary)? Training with a full Softmax is slow in this case, since all of the classes are evaluated for every training example. Candidate Sampling training algorithms can speed up your step times by only considering a small randomly-chosen subset of contrastive classes (called candidates) for each batch of training examples.

See our Candidate Sampling Algorithms Reference

Sampled Loss Functions

TensorFlow provides the following sampled loss functions for faster training.

```
tf.nn.nce_loss(weights, biases, inputs, labels,
num_sampled, num_classes, num_true=1,
sampled_values=None, remove_accidental_hits=False,
partition strategy='mod', name='nce loss')
```

Computes and returns the noise-contrastive estimation training loss.

See <u>Noise-contrastive estimation: A new estimation principle for unnormalized statistical models</u>. Also see our <u>Candidate Sampling Algorithms Reference</u>

Note: In the case where num_true > 1, we assign to each target class the target probability 1 / num_true so that the target probabilities sum to 1 per-example.

Note: It would be useful to allow a variable number of target classes per example. We hope to provide this functionality in a future release. For now, if you have a variable number of target classes, you can pad them out to a constant number by either repeating them or by padding with an otherwise unused class.

Args:

- weights: A Tensor of shape [num_classes, dim], or a list
 of Tensor objects whose concatenation along dimension 0 has shape
 [num_classes, dim]. The (possibly-partitioned) class embeddings.
- biases: A Tensor of shape [num classes]. The class biases.
- inputs: A Tensor of shape [batch_size, dim]. The forward activations of the input network.
- labels: A Tensor of type int64 and shape [batch_size,
 num_true]. The target classes.
- num_sampled: An int. The number of classes to randomly sample per batch.
- num_classes: An int. The number of possible classes.
- num_true: An int. The number of target classes per training example.
- (sampled_candidates, true_expected_count, sampled_expected_count) returned by a *_candidate_sampler function. (if None, we
 - default tolog uniform candidate sampler)

sampled values: a tuple of

remove_accidental_hits: A bool. Whether to remove "accidental hits" where a sampled class equals one of the target classes. If set to True, this is a "Sampled Logistic" loss instead of NCE, and we are

learning to generate log-odds instead of log probabilities. See our Candidate Sampling Algorithms Reference. Default is False.

- partition_strategy: A string specifying the partitioning strategy,
 relevant if len(weights) > 1. Currently "div" and "mod" are
 supported. Default is "mod". See tf.nn.embedding_lookup for more details.
- name: A name for the operation (optional).

Returns:

A batch size 1-D tensor of per-example NCE losses.

```
tf.nn.sampled_softmax_loss(weights, biases, inputs,
labels, num_sampled, num_classes, num_true=1,
sampled_values=None, remove_accidental_hits=True,
partition strategy='mod', name='sampled softmax loss')
```

Computes and returns the sampled softmax training loss.

This is a faster way to train a softmax classifier over a huge number of classes.

This operation is for training only. It is generally an underestimate of the full softmax loss.

At inference time, you can compute full softmax probabilities with the expressiontf.nn.softmax(tf.matmul(inputs, weights) + biases).

See our <u>Candidate Sampling Algorithms Reference</u> Also see Section 3 of <u>Jean et al., 2014</u> (pdf) for the math.

Args:

- weights: A Tensor of shape [num_classes, dim], or a list
 of Tensor objects whose concatenation along dimension 0 has shape
 [num_classes, dim]. The (possibly-sharded) class embeddings.
- biases: A Tensor of shape [num classes]. The class biases.
- inputs: A Tensor of shape [batch_size, dim]. The forward activations of the input network.
- labels: A Tensor of type int64 and shape [batch_size,
 num_true]. The target classes. Note that this format differs from
 the labels argument of nn.softmax cross entropy with logits.
- num_sampled: An int. The number of classes to randomly sample per batch.
- num classes: An int. The number of possible classes.
- num_true: An int. The number of target classes per training example.
- sampled_values: a tuple of

 (sampled_candidates, true_expected_count, sampled_expected_c

 ount) returned by a *_candidate_sampler function. (if None, we

 default tolog uniform candidate sampler)
- remove_accidental_hits: A bool. whether to remove "accidental
 hits" where a sampled class equals one of the target classes. Default
 is True.
- partition_strategy: A string specifying the partitioning strategy,
 relevant if len(weights) > 1. Currently "div" and "mod" are
 supported. Default is "mod". See tf.nn.embedding_lookup for more details.
- name: A name for the operation (optional).

Returns:

A batch size 1-D tensor of per-example sampled softmax losses.

Candidate Samplers

TensorFlow provides the following samplers for randomly sampling candidate classes when using one of the sampled loss functions above.

tf.nn.uniform_candidate_sampler(true_classes, num_true,
num_sampled, unique, range_max, seed=None, name=None)

Samples a set of classes using a uniform base distribution.

This operation randomly samples a tensor of sampled classes (sampled candidates) from the range of integers [0, range max].

The elements of sampled_candidates are drawn without replacement (if unique=True) or with replacement (if unique=False) from the base distribution.

The base distribution for this operation is the uniform distribution over the range of integers [0, range_max].

In addition, this operation returns

tensors true_expected_count and sampled_expected_countrepres enting the number of times each of the target classes (true_classes) and the sampled classes (sampled_candidates) is expected to occur in an average tensor of sampled classes. These values correspond to Q(y|x) defined in this document.

If unique=True, then these are post-rejection probabilities and we compute them approximately.

Args:

- true_classes: A Tensor of type int64 and shape [batch_size,
 num true]. The target classes.
- num_true: An int. The number of target classes per training example.
- num_sampled: An int. The number of classes to randomly sample per batch.
- unique: A bool. Determines whether all sampled classes in a batch are unique.
- range_max: An int. The number of possible classes.
- seed: An int. An operation-specific seed. Default is 0.
- name: A name for the operation (optional).

Returns:

- sampled_candidates: A tensor of type int64 and
 shape [num sampled]. The sampled classes.
- true_expected_count: A tensor of type float. Same shape
 as true_classes. The expected counts under the sampling
 distribution of each of true classes.
- sampled_expected_count: A tensor of type float. Same shape
 as sampled_candidates. The expected counts under the sampling
 distribution of each of sampled candidates.

```
tf.nn.log_uniform_candidate_sampler(true_classes,
num_true, num_sampled, unique, range_max, seed=None,
name=None)
```

Samples a set of classes using a log-uniform (Zipfian) base distribution.

This operation randomly samples a tensor of sampled classes (sampled_candidates) from the range of integers [0, range_max].

The elements of sampled_candidates are drawn without replacement (if unique=True) or with replacement (if unique=False) from the base distribution.

The base distribution for this operation is an approximately loguniform or Zipfian distribution:

```
P(class) = (log(class + 2) - log(class + 1)) / log(range max + 1)
```

This sampler is useful when the target classes approximately follow such a distribution - for example, if the classes represent words in a lexicon sorted in decreasing order of frequency. If your classes are not ordered by decreasing frequency, do not use this op.

In addition, this operation returns

tensors true_expected_count and sampled_expected_countrepres enting the number of times each of the target classes (true_classes) and the sampled classes (sampled_candidates) is expected to occur in an average tensor of sampled classes. These values correspond to Q(y|x) defined in this document.

If unique=True, then these are post-rejection probabilities and we compute them approximately.

Args:

- true_classes: A Tensor of type int64 and shape [batch_size,
 num true]. The target classes.
- num_true: An int. The number of target classes per training example.
- num_sampled: An int. The number of classes to randomly sample per batch.
- unique: A bool. Determines whether all sampled classes in a batch are unique.
- range max: An int. The number of possible classes.
- seed: An int. An operation-specific seed. Default is 0.
- name: A name for the operation (optional).

Returns:

- sampled_candidates: A tensor of type int64 and
 shape [num sampled]. The sampled classes.
- true_expected_count: A tensor of type float. Same shape
 as true_classes. The expected counts under the sampling
 distribution of each of true classes.
- sampled_expected_count: A tensor of type float. Same shape
 as sampled_candidates. The expected counts under the sampling
 distribution of each of sampled_candidates.

```
tf.nn.learned_unigram_candidate_sampler(true_classes,
num_true, num_sampled, unique, range_max, seed=None,
name=None)
```

Samples a set of classes from a distribution learned during training.

This operation randomly samples a tensor of sampled classes (sampled candidates) from the range of integers [0, range max].

The elements of sampled_candidates are drawn without replacement (if unique=True) or with replacement (if unique=False) from the base distribution.

The base distribution for this operation is constructed on the fly during training. It is a unigram distribution over the target classes seen so far during training. Every integer in [0, range_max] begins with a weight of 1, and is incremented by 1 each time it is seen as a target class. The base distribution is not saved to checkpoints, so it is reset when the model is reloaded. In addition, this operation returns

tensors true_expected_count and sampled_expected_countrepres enting the number of times each of the target classes (true_classes) and the sampled classes (sampled_candidates) is expected to occur in an average tensor of sampled classes. These values correspond to Q(y|x) defined in this document.

If unique=True, then these are post-rejection probabilities and we compute them approximately.

Args:

- true_classes: A Tensor of type int64 and shape [batch_size,
 num true]. The target classes.
- num_true: An int. The number of target classes per training example.

- num_sampled: An int. The number of classes to randomly sample per batch.
- unique: A bool. Determines whether all sampled classes in a batch are unique.
- range max: An int. The number of possible classes.
- seed: An int. An operation-specific seed. Default is 0.
- name: A name for the operation (optional).

Returns:

- sampled_candidates: A tensor of type int64 and
 shape [num sampled]. The sampled classes.
- true_expected_count: A tensor of type float. Same shape
 as true_classes. The expected counts under the sampling
 distribution of each of true_classes.
- sampled_expected_count: A tensor of type float. Same shape
 as sampled_candidates. The expected counts under the sampling
 distribution of each of sampled candidates.

tf.nn.fixed_unigram_candidate_sampler(true_classes,
num_true, num_sampled, unique, range_max, vocab_file='',
distortion=1.0, num_reserved_ids=0, num_shards=1,
shard=0, unigrams=(), seed=None, name=None)

Samples a set of classes using the provided (fixed) base distribution.

This operation randomly samples a tensor of sampled classes (sampled candidates) from the range of integers [0, range max].

The elements of sampled_candidates are drawn without replacement (if unique=True) or with replacement (if unique=False) from the base distribution.

The base distribution is read from a file or passed in as an in-memory array. There is also an option to skew the distribution by applying a distortion power to the weights.

In addition, this operation returns

tensors true_expected_count and sampled_expected_countrepres enting the number of times each of the target classes (true_classes) and the sampled classes (sampled_candidates) is expected to occur in an average tensor of sampled classes. These values correspond to Q(y|x) defined in this document.

If unique=True, then these are post-rejection probabilities and we compute them approximately.

Args:

- true_classes: A Tensor of type int64 and shape [batch_size,
 num true]. The target classes.
- num_true: An int. The number of target classes per training example.
- num_sampled: An int. The number of classes to randomly sample per batch.
- unique: A bool. Determines whether all sampled classes in a batch are unique.
- range max: An int. The number of possible classes.

- vocab_file: Each valid line in this file (which should have a CSV-like format) corresponds to a valid word ID. IDs are in sequential order, starting from num_reserved_ids. The last entry in each line is expected to be a value corresponding to the count or relative probability. Exactly one of vocab_file and unigrams needs to be passed to this operation.
- distortion: The distortion is used to skew the unigram probability distribution. Each weight is first raised to the distortion's power before adding to the internal unigram distribution. As a result, distortion =
 1.0 gives regular unigram sampling (as defined by the vocab file),
 and distortion = 0.0 gives a uniform distribution.
- num_reserved_ids: Optionally some reserved IDs can be added in the range [0, num_reserved_ids] by the users. One use case is that a special unknown word token is used as ID 0. These IDs will have a sampling probability of 0.
- num_shards: A sampler can be used to sample from a subset of the
 original range in order to speed up the whole computation through
 parallelism. This parameter (together with shard) indicates the
 number of partitions that are being used in the overall computation.
- shard: A sampler can be used to sample from a subset of the original range in order to speed up the whole computation through parallelism. This parameter (together with num_shards) indicates the particular partition number of the operation, when partitioning is being used.
- unigrams: A list of unigram counts or probabilities, one per ID in sequential order. Exactly one ofvocab_file and unigrams should be passed to this operation.
- seed: An int. An operation-specific seed. Default is 0.
- name: A name for the operation (optional).

Returns:

- sampled_candidates: A tensor of type int64 and
 shape [num sampled]. The sampled classes.
- true_expected_count: A tensor of type float. Same shape as true_classes. The expected counts under the sampling distribution of each of true classes.
- sampled_expected_count: A tensor of type float. Same shape
 as sampled_candidates. The expected counts under the sampling
 distribution of each of sampled candidates.

Miscellaneous candidate sampling utilities

```
tf.nn.compute_accidental_hits(true_classes,
  sampled_candidates, num_true, seed=None, name=None)
Compute the position ids
```

in sampled candidates matching true classes.

In Candidate Sampling, this operation facilitates virtually removing sampled classes which happen to match target classes. This is done in Sampled Softmax and Sampled Logistic.

See our Candidate Sampling Algorithms Reference.

We presuppose that the sampled_candidates are unique.

We call it an 'accidental hit' when one of the target classes matches one of the sampled classes. This operation reports accidental hits as triples (index, id, weight), where index represents the row

number intrue_classes, id represents the position
in sampled_candidates, and weight is -FLOAT_MAX.
The result of this op should be passed through
a sparse_to_dense operation, then added to the logits of the
sampled classes. This removes the contradictory effect of
accidentally sampling the true target classes as noise classes for the
same example.

Args:

- true_classes: A Tensor of type int64 and shape [batch_size,
 num true]. The target classes.
- sampled_candidates: A tensor of type int64 and
 shape [num_sampled]. The sampled_candidates output of CandidateSampler.
- num_true: An int. The number of target classes per training example.
- seed: An int. An operation-specific seed. Default is 0.
- name: A name for the operation (optional).

Returns:

- indices: A Tensor of type int32 and
 shape [num_accidental_hits]. Values indicate rows
 intrue classes.
- ids: A Tensor of type int64 and shape [num_accidental_hits].
 Values indicate positions insampled candidates.

weights: A Tensor of type float and

shape [num_accidental_hits]. Each value is -FLOAT_MAX.

Running Graphs

This library contains classes for launching graphs and executing operations.

The <u>basic usage</u> guide has examples of how a graph is launched in a tf. Session.

Session management

```
class tf.Session
```

A class for running TensorFlow operations.

A Session object encapsulates the environment in

which Operation objects are executed, and Tensor objects are evaluated. For example:

```
# Build a graph.
a = tf.constant(5.0)
b = tf.constant(6.0)
c = a * b

# Launch the graph in a session.
sess = tf.Session()

# Evaluate the tensor `c`.
print(sess.run(c))
```

A session may own resources, such as <u>variables</u>, <u>queues</u>, and <u>readers</u>. It is important to release these resources when they are no longer required. To do this, either invoke the <u>close()</u> method on the session, or use the session as a context manager. The following two examples are equivalent:

```
# Using the `close()` method.
sess = tf.Session()
sess.run(...)
sess.close()

# Using the context manager.
with tf.Session() as sess:
    sess.run(...)
```

The Configeroto protocol buffer exposes various configuration

options for a session. For example, to create a session that uses soft constraints for device placement, and log the resulting placement decisions, create a session as follows:

```
# Launch the graph in a session that allows soft device placement
and
# logs the placement decisions.
```

```
tf.Session.__init__(target='', graph=None, config=None)
```

Creates a new TensorFlow session.

If no <code>graph</code> argument is specified when constructing the session, the default graph will be launched in the session. If you are using more than one graph (created with tf.Graph() in the same process, you will have to use different sessions for each graph, but each graph can be used in multiple sessions. In this case, it is often clearer to pass the graph to be launched explicitly to the session constructor.

Args:

- target: (Optional.) The execution engine to connect to. Defaults to using an in-process engine. At present, no value other than the empty string is supported.
- graph: (Optional.) The Graph to be launched (described above).
- config: (Optional.) A ConfigProto protocol buffer with configuration options for the session.

```
tf.Session.run(fetches, feed dict=None)
```

Runs the operations and evaluates the tensors in fetches.

This method runs one "step" of TensorFlow computation, by running the necessary graph fragment to execute every Operation and

evaluate every Tensor in fetches, substituting the values in feed dict for the corresponding input values.

The fetches argument may be a list of graph elements or a single graph element, and these determine the return value of this method. A graph element can be one of the following types:

- If the *i*th element of fetches is an Operation, the *i*th return value will be None.
- If the *i*th element of fetches is a Tensor, the *i*th return value will be a numpy ndarray containing the value of that tensor.
- If the *i*th element of fetches is a SparseTensor, the *i*th return value will be a SparseTensorValueContaining the value of that sparse tensor.

The optional feed_dict argument allows the caller to override the value of tensors in the graph. Each key infeed_dict can be one of the following types:

- If the key is a Tensor, the value may be a Python scalar, string, list, or numpy ndarray that can be converted to the same dtype as that tensor. Additionally, if the key is a placeholder, the shape of the value will be checked for compatibility with the placeholder.
- If the key is a SparseTensor, the value should be

a SparseTensorValue.

Args:

 fetches: A single graph element, or a list of graph elements (described above).

•	feed_dict: A dictionary that maps graph elements to values (described above).
	Returns:
	Either a single value if fetches is a single graph element, or a list of
	values if fetches is a list (described above).
	Raises:
•	RuntimeError: If this Session is in an invalid state (e.g. has been closed).
•	TypeError: If fetches or feed_dict keys are of an inappropriate .
•	type. ValueError: If fetches or feed dict keys are invalid or refer to
	a Tensor that doesn't exist.
	tf.Session.close()
	Closes this session.
	Calling this method frees all resources associated with the session.
	Raises:
•	RuntimeError: If an error occurs while closing the session.

```
tf.Session.graph
```

The graph that was launched in this session.

```
tf.Session.as_default()
```

Returns a context manager that makes this object the default session.

Use with the with keyword to specify that calls

to Operation.run() or Tensor.run() should be executed in this session.

```
c = tf.constant(..)
sess = tf.Session()

with sess.as_default():
   assert tf.get_default_session() is sess
   print(c.eval())
```

To get the current default session, use tf.get default session().

N.B. The as_default context manager does not close the session when you exit the context, and you must close the session explicitly.

```
c = tf.constant(...)
sess = tf.Session()
with sess.as_default():
   print(c.eval())
# ...
with sess.as_default():
   print(c.eval())
sess.close()
```

Alternatively, you can use with tf.Session(): to create a session that is automatically closed on exiting the context, including when an uncaught exception is raised.

N.B. The default graph is a property of the current thread. If you create a new thread, and wish to use the default session in that

thread, you must explicitly add a with sess.as_default(): in that thread's function.

Returns:

A context manager using this session as the default session.

```
class tf.InteractiveSession
```

A TensorFlow Session for use in interactive contexts, such as a shell.

The only difference with a regular Session is that

an InteractiveSession installs itself as the default session on construction. The

methods Tensor.eval() and Operation.run() will use that session to run ops.

This is convenient in interactive shells and <u>IPython notebooks</u>, as it avoids having to pass an explicit Sessionobject to run ops.

For example:

```
sess = tf.InteractiveSession()
a = tf.constant(5.0)
b = tf.constant(6.0)
c = a * b
# We can just use 'c.eval()' without passing 'sess'
print(c.eval())
sess.close()
```

Note that a regular session installs itself as the default session when it is created in a with statement. The common usage in non-interactive programs is to follow that pattern:

```
a = tf.constant(5.0)
b = tf.constant(6.0)
c = a * b
```

```
with tf.Session():
    # We can also use 'c.eval()' here.
print(c.eval())
```

```
tf.InteractiveSession.__init__(target='', graph=None,
config=None)
```

Creates a new interactive TensorFlow session.

If no graph argument is specified when constructing the session, the default graph will be launched in the session. If you are using more than one graph (created with tf.Graph() in the same process, you will have to use different sessions for each graph, but each graph can be used in multiple sessions. In this case, it is often clearer to pass the graph to be launched explicitly to the session constructor.

Args:

- target: (Optional.) The execution engine to connect to. Defaults to using an in-process engine. At present, no value other than the empty string is supported.
- graph: (Optional.) The Graph to be launched (described above).
- config: (Optional) ConfigProto proto used to configure the session.

```
tf.InteractiveSession.close()
```

Closes an InteractiveSession.

```
tf.get default session()
```

Returns the default session for the current thread.

The returned Session will be the innermost session on which

a Session or Session.as default() context has been entered.

NOTE: The default session is a property of the current thread. If you create a new thread, and wish to use the default session in that thread, you must explicitly add a with sess.as_default(): in that thread's function.

Returns:

The default Session being used in the current thread.

Error classes

```
class tf.OpError
```

A generic error that is raised when TensorFlow execution fails.

Whenever possible, the session will raise a more specific subclass of Operror from the tf.errors module.

tf.OpError.op

The operation that failed, if known.

N.B. If the failed op was synthesized at runtime, e.g. a <code>Send</code> or <code>Recv</code> op, there will be no corresponding <code>Operation</code> object. In that case, this will return <code>None</code>, and you should instead use the <code>OpError.node_def</code> to discover information about the op.

Returns:

The Operation that failed, or None.

```
tf.OpError.node_def
```

The NodeDef proto representing the op that failed.

Other Methods

tf.OpError.__init__(node_def, op, message, error_code)

Creates a new OpError indicating that a particular op failed.

Args:

- node_def: The graph_pb2.NodeDef proto representing the op that failed.
- op: The ops.Operation that failed, if known; otherwise None.
- message: The message string describing the failure.
- error_code: The error_codes_pb2.Code describing the error.

```
tf.OpError.error code
```

The integer error code that describes the error.

```
tf.OpError.message
```

The error message that describes the error.

```
class tf.errors.CancelledError
```

Raised when an operation or step is cancelled.

For example, a long-running operation (e.g. queue.enqueue() may be cancelled by running another operation

(e.g. queue.close (cancel_pending_enqueues=True), or by <u>closing</u> the session. A step that is running such a long-running operation will fail by raising <code>CancelledError</code>.

```
tf.errors.CancelledError.__init__(node_def, op, message)
Creates a CancelledError.
```

Unknown error.

An example of where this error may be returned is if a Status value received from another address space belongs to an error-space that is not known to this address space. Also errors raised by APIs that do not return enough error information may be converted to this error.

```
tf.errors.UnknownError.__init__(node_def, op, message,
error_code=2)
```

Creates an UnknownError.

```
class tf.errors.InvalidArgumentError
```

Raised when an operation receives an invalid argument.

This may occur, for example, if an operation is receives an input tensor that has an invalid value or shape. For example,

the tf.matmul() op will raise this error if it receives an input that is not a matrix, and thetf.reshape() op will raise this error if the new shape does not match the number of elements in the input tensor.

```
tf.errors.InvalidArgumentError.__init__(node_def, op,
message)
```

Creates an InvalidArgumentError.

```
class tf.errors.DeadlineExceededError
```

Raised when a deadline expires before an operation could complete.

This exception is not currently used.

```
tf.errors.DeadlineExceededError.__init__(node_def, op,
message)
```

Creates a DeadlineExceededError.

```
class tf.errors.NotFoundError
```

Raised when a requested entity (e.g., a file or directory) was not found.

For example, running the tf.WholeFileReader.read() operation could raise NotFoundError if it receives the name of a file that does not exist.

```
tf.errors.NotFoundError.__init__(node_def, op, message)
Creates a NotFoundError.
```

class tf.errors.AlreadyExistsError

Raised when an entity that we attempted to create already exists.

For example, running an operation that saves a file (e.g. tf.train.Saver.save()) could potentially raise this exception if an explicit filename for an existing file was passed.

```
tf.errors.AlreadyExistsError.__init__(node_def, op,
message)
```

Creates an AlreadyExistsError.

```
class tf.errors.PermissionDeniedError
```

Raised when the caller does not have permission to run an operation.

For example, running the tf.WholeFileReader.read() operation could raise PermissionDeniedErrorif it receives the name of a file for which the user does not have the read file permission.

```
tf.errors.PermissionDeniedError.__init__(node_def, op,
message)
```

Creates a PermissionDeniedError.

```
class tf.errors.UnauthenticatedError
```

The request does not have valid authentication credentials.

This exception is not currently used.

tf.errors.UnauthenticatedError.__init__(node_def, op,
message)

Creates an UnauthenticatedError.

class tf.errors.ResourceExhaustedError

Some resource has been exhausted.

For example, this error might be raised if a per-user quota is exhausted, or perhaps the entire file system is out of space.

tf.errors.ResourceExhaustedError.__init__(node_def, op,
message)

Creates a ResourceExhaustedError.

class tf.errors.FailedPreconditionError

Operation was rejected because the system is not in a state to execute it.

This exception is most commonly raised when running an operation that reads a tf.variable before it has been initialized.

tf.errors.FailedPreconditionError.__init__(node_def, op,
message)

Creates a FailedPreconditionError.

class tf.errors.AbortedError

The operation was aborted, typically due to a concurrent action.

For example, running a queue.enqueue() operation may raise AbortedError if a queue.close() operation previously ran.

tf.errors.AbortedError.__init__(node_def, op, message)
Creates an AbortedError.

class tf.errors.OutOfRangeError

Raised when an operation executed past the valid range.

This exception is raised in "end-of-file" conditions, such as when a queue.dequeue() operation is blocked on an empty queue, and a queue.close() operation executes.

```
tf.errors.OutOfRangeError.__init__(node_def, op, message)
Creates an OutOfRangeError.
```

```
class tf.errors.UnimplementedError
```

Raised when an operation has not been implemented.

Some operations may raise this error when passed otherwise-valid arguments that it does not currently support. For example, running the tf.nn.max_pool() operation would raise this error if pooling was requested on the batch dimension, because this is not yet supported.

```
tf.errors.UnimplementedError.__init__(node_def, op,
message)
```

Creates an UnimplementedError.

```
class tf.errors.InternalError
```

Raised when the system experiences an internal error.

This exception is raised when some invariant expected by the runtime has been broken. Catching this exception is not recommended.

```
tf.errors.InternalError. init (node def, op, message)
```

Creates an InternalError.

```
class tf.errors.UnavailableError
```

Raised when the runtime is currently unavailable.

This exception is not currently used.

```
tf.errors.UnavailableError.__init__(node_def, op,
message)
```

Creates an UnavailableError.

```
class tf.errors.DataLossError
```

Raised when unrecoverable data loss or corruption is encountered.

For example, this may be raised by running

a tf.wholeFileReader.read() operation, if the file is truncated while it is being read.

```
tf.errors.DataLossError.__init__(node_def, op, message)
Creates a DataLossError.
```

- tf.train.import meta graph (meta graph or file)

This library provides a set of classes and functions that helps train models.

Optimizers

The Optimizer base class provides methods to compute gradients for a loss and apply gradients to variables. A collection of subclasses implement classic optimization algorithms such as GradientDescent and Adagrad.

You never instantiate the Optimizer class itself, but instead instantiate one of the subclasses.

class tf.train.Optimizer

Base class for optimizers.

This class defines the API to add Ops to train a model. You never use this class directly, but instead instantiate one of its subclasses

SUCh as GradientDescentOptimizer, AdagradOptimizer,

Or MomentumOptimizer.

Usage

```
# Create an optimizer with the desired parameters.
opt = GradientDescentOptimizer(learning_rate=0.1)
# Add Ops to the graph to minimize a cost by updating a list of
variables.
# "cost" is a Tensor, and the list of variables contains
tf.Variable
# objects.
opt_op = opt.minimize(cost, var_list=<list of variables>)
```

In the training program you will just have to run the returned Op.

```
# Execute opt_op to do one step of training:
opt_op.run()
```

Processing gradients before applying them.

Calling minimize() takes care of both computing the gradients and applying them to the variables. If you want to process the gradients before applying them you can instead use the optimizer in three steps:

- 1. Compute the gradients with compute gradients().
- 2. Process the gradients as you wish.
- 3. Apply the processed gradients with apply_gradients().

Example:

```
# Create an optimizer.
opt = GradientDescentOptimizer(learning_rate=0.1)
# Compute the gradients for a list of variables.
```

```
grads_and_vars = opt.compute_gradients(loss, <list of variables>)

# grads_and_vars is a list of tuples (gradient, variable). Do
whatever you
# need to the 'gradient' part, for example cap them, etc.
capped_grads_and_vars = [(MyCapper(gv[0]), gv[1])) for gv in
grads_and_vars]

# Ask the optimizer to apply the capped gradients.
opt.apply_gradients(capped_grads_and_vars)
```

```
tf.train.Optimizer.__init__(use_locking, name)
```

Create a new Optimizer.

This must be called by the constructors of subclasses.

Args:

- use_locking: Bool. If True apply use locks to prevent concurrent updates to variables.
- name: A non-empty string. The name to use for accumulators created for the optimizer.

Raises:

• ValueError: If name is malformed.

```
tf.train.Optimizer.minimize(loss, global_step=None,
var_list=None, gate_gradients=1, aggregation_method=None,
colocate_gradients_with_ops=False, name=None)
```

Add operations to minimize loss by updating var_list.

This method simply combines

calls compute_gradients() and apply_gradients(). If you want to process the gradient before applying them

call compute_gradients() and apply_gradients() explicitly instead of using this function.

Args:

- loss: A Tensor containing the value to minimize.
- global_step: Optional variable to increment by one after the variables have been updated.
- var_list: Optional list of Variable objects to update to
 minimize loss. Defaults to the list of variables collected in the graph
 under the key GraphKeys.TRAINABLE_VARIABLES.
- gate_gradients: How to gate the computation of gradients. Can be GATE_NONE, GATE_OP, orGATE_GRAPH.
- aggregation_method: Specifies the method used to combine gradient terms. Valid values are defined in the class AggregationMethod.
- colocate_gradients_with_ops: If True, try colocating gradients with the corresponding op.
- name: Optional name for the returned operation.

Returns:

An Operation that updates the variables in var list.

If global_step was not None, that operation also
increments global step.

Raises:

ValueError: If some of the variables are not Variable objects.

```
tf.train.Optimizer.compute_gradients(loss, var_list=None,
gate_gradients=1, aggregation_method=None,
colocate gradients with ops=False)
```

Compute gradients of loss for the variables in var list.

This is the first part of minimize(). It returns a list of (gradient, variable) pairs where "gradient" is the gradient for "variable". Note that "gradient" can be a Tensor, an IndexedSlices, or None if there is no gradient for the given variable.

Args:

- loss: A Tensor containing the value to minimize.
- var_list: Optional list of tf. Variable to update to minimize loss.
 Defaults to the list of variables collected in the graph under the key GraphKey. TRAINABLE_VARIABLES.
- gate_gradients: How to gate the computation of gradients. Can be GATE_NONE, GATE_OP, orGATE_GRAPH.

- aggregation_method: Specifies the method used to combine gradient terms. Valid values are defined in the class AggregationMethod.
- colocate_gradients_with_ops: If True, try colocating gradients with the corresponding op.

Returns:

A list of (gradient, variable) pairs.

Raises:

- TypeError: If var_list contains anything else than Variable objects.
- ValueError: If some arguments are invalid.

```
tf.train.Optimizer.apply_gradients(grads_and_vars,
global_step=None, name=None)
```

Apply gradients to variables.

This is the second part of minimize(). It returns an Operation that applies gradients.

Args:

grads_and_vars: List of (gradient, variable) pairs as returned
 by compute gradients().

- global_step: Optional variable to increment by one after the variables have been updated.
- name: Optional name for the returned operation. Default to the name passed to the Optimizer constructor.

Returns:

An Operation that applies the specified gradients.

If global_step was not None, that operation also increments global step.

Raises:

- TypeError: If grads and vars is malformed.
- ValueError: If none of the variables have gradients.

Gating Gradients

Both minimize() and compute_gradients() accept

a gate_gradient argument that controls the degree of parallelism during the application of the gradients.

The possible values are: <code>gate_none</code>, <code>gate_op</code>, and <code>gate_graph</code>.

GATE_NONE: Compute and apply gradients in parallel. This provides the maximum parallelism in execution, at the cost of some non-reproducibility in the results. For example the two gradients of matmul depend on the input values: With GATE_NONE one of the gradients could be applied to one of the inputs before the other gradient is computed resulting in non-reproducible results.

GATE_OP: For each Op, make sure all gradients are computed before they are used. This prevents race conditions for Ops that generate gradients for multiple inputs where the gradients depend on the inputs.

GATE_GRAPH: Make sure all gradients for all variables are computed before any one of them is used. This provides the least parallelism but can be useful if you want to process all gradients before applying any of them.

Slots

Some optimizer subclasses, such

as MomentumOptimizer and AdagradOptimizer allocate and manage additional variables associated with the variables to train. These are called *Slots*. Slots have names and you can ask the optimizer for the names of the slots that it uses. Once you have a slot name you can ask the optimizer for the variable it created to hold the slot value.

This can be useful if you want to log debug a training algorithm, report stats about the slots, etc.

```
tf.train.Optimizer.get_slot_names()
```

Return a list of the names of slots created by the Optimizer.

```
See get slot().
```

Returns:

A list of strings.

Return a slot named name created for var by the Optimizer.

Some Optimizer subclasses use additional variables. For example Momentum and Adagrad use variables to accumulate updates. This method gives access to these Variable objects if for

Use get_slot_names() to get the list of slot names created by
the Optimizer.

Args:

- var: A variable passed to minimize() or apply gradients().
- name: A string.

some reason you need them.

Returns:

The Variable for the slot if it was created, None otherwise.

class tf.train.GradientDescentOptimizer

Optimizer that implements the gradient descent algorithm.

```
tf.train.GradientDescentOptimizer.__init__ (learning_rate,
use locking=False, name='GradientDescent')
```

Construct a new gradient descent optimizer.

Args:

- learning_rate: A Tensor or a floating point value. The learning rate to use.
- use locking: If True use locks for update operations.
- name: Optional name prefix for the operations created when applying gradients. Defaults to "GradientDescent".

```
class tf.train.AdagradOptimizer
```

Optimizer that implements the Adagrad algorithm.

See this paper.

```
tf.train.AdagradOptimizer.__init__(learning_rate,
initial_accumulator_value=0.1, use_locking=False,
name='Adagrad')
```

Construct a new Adagrad optimizer.

Args:

- learning rate: A Tensor or a floating point value. The learning rate.
- initial_accumulator_value: A floating point value. Starting value for the accumulators, must be positive.
- use_locking: If True use locks for update operations.
- name: Optional name prefix for the operations created when applying gradients. Defaults to "Adagrad".

Raises:

• ValueError: If the initial accumulator value is invalid.

class tf.train.MomentumOptimizer

Optimizer that implements the Momentum algorithm.

```
tf.train.MomentumOptimizer.__init__(learning_rate,
momentum, use_locking=False, name='Momentum')
```

Construct a new Momentum optimizer.

Args:

- learning_rate: A Tensor or a floating point value. The learning rate.
- momentum: A Tensor or a floating point value. The momentum.
- use_locking: If True use locks for update operations.
- name: Optional name prefix for the operations created when applying gradients. Defaults to "Momentum".

class tf.train.AdamOptimizer

Optimizer that implements the Adam algorithm.

See Kingma et. al., 2014 (pdf).

```
tf.train.AdamOptimizer.__init__(learning_rate=0.001,
beta1=0.9, beta2=0.999, epsilon=1e-08, use_locking=False,
name='Adam')
```

Construct a new Adam optimizer.

Initialization:

```
m_0 < 0 (Initialize initial 1st moment vector) v_0 < 0 (Initialize initial 2nd moment vector) t < 0 (Initialize timestep)
```

The update rule for variable with gradient g uses an optimization described at the end of section2 of the paper:

```
t <- t + 1
lr_t <- learning_rate * sqrt(1 - beta2^t) / (1 - beta1^t)

m_t <- beta1 * m_{t-1} + (1 - beta1) * g
v_t <- beta2 * v_{t-1} + (1 - beta2) * g * g
variable <- variable - lr_t * m_t / (sqrt(v_t) + epsilon)</pre>
```

The default value of 1e-8 for epsilon might not be a good default in general. For example, when training an Inception network on ImageNet a current good choice is 1.0 or 0.1.

Args:

- learning rate: A Tensor or a floating point value. The learning rate.
- beta1: A float value or a constant float tensor. The exponential decay rate for the 1st moment estimates.
- beta2: A float value or a constant float tensor. The exponential decay rate for the 2nd moment estimates.
- epsilon: A small constant for numerical stability.
- use_locking: If True use locks for update operations.

 name: Optional name for the operations created when applying gradients. Defaults to "Adam".

```
class tf.train.FtrlOptimizer
```

Optimizer that implements the FTRL algorithm.

```
tf.train.FtrlOptimizer.__init__(learning_rate,
learning_rate_power=-0.5, initial_accumulator_value=0.1,
l1_regularization_strength=0.0,
l2_regularization_strength=0.0, use_locking=False,
name='Ftrl')
```

Construct a new FTRL optimizer.

The Ftrl-proximal algorithm, abbreviated for Follow-the-regularized-leader, is described in the paper Ad Click Prediction: a View from the Trenches.

It can give a good performance vs. sparsity tradeoff.

Ftrl-proximal uses its own global base learning rate and can behave like Adagrad withlearning_rate_power=-0.5, or like gradient descent with learning rate power=0.0.

The effective learning rate is adjusted per parameter, relative to this base learning rate as:

```
effective_learning_rate_i = (learning_rate /
    pow(k + summed_squared_gradients_for_i, learning_rate_power));
```

where k is the small constant initial_accumulator_value.

Note that the real regularization coefficient of $|w|^2$ for objective function is 1 / lambda_2 if specifying 12 = lambda_2 as argument when using this function.

Args:

- learning rate: A float value or a constant float Tensor.
- learning rate power: A float value, must be less or equal to zero.
- initial_accumulator_value: The starting value for accumulators.
 Only positive values are allowed.
- 11_regularization_strength: A float value, must be greater than or equal to zero.
- 12_regularization_strength: A float value, must be greater than or equal to zero.
- use_locking: If True use locks for update operations.
- name: Optional name prefix for the operations created when applying gradients. Defaults to "Ftrl".

Raises:

• ValueError: If one of the arguments is invalid.

class tf.train.RMSPropOptimizer

Optimizer that implements the RMSProp algorithm.

See the paper.

```
tf.train.RMSPropOptimizer.__init__(learning_rate,
decay=0.9, momentum=0.0, epsilon=1e-10,
use locking=False, name='RMSProp')
```

Construct a new RMSProp optimizer.

Args:

- learning_rate: A Tensor or a floating point value. The learning rate.
- decay: Discounting factor for the history/coming gradient
- momentum: A scalar tensor.
- epsilon: Small value to avoid zero denominator.
- use locking: If True use locks for update operation.
- name: Optional name prefix for the operations created when applying gradients. Defaults to "RMSProp".

Gradient Computation

TensorFlow provides functions to compute the derivatives for a given TensorFlow computation graph, adding operations to the graph. The optimizer classes automatically compute derivatives on your graph, but creators of new Optimizers or expert users can call the lower-level functions below.

```
tf.gradients(ys, xs, grad_ys=None, name='gradients',
colocate_gradients_with_ops=False, gate_gradients=False,
aggregation method=None)
```

Constructs symbolic partial derivatives of ys w.r.t. x in xs.

ys and xs are each a Tensor or a list of tensors. $grad_ys$ is a list of Tensor, holding the gradients received by the ys. The list must be the same length as ys.

gradients () adds ops to the graph to output the partial derivatives of ys with respect to xs. It returns a list of tensor of length len(xs) where each tensor is the sum(dy/dx) for y in ys. grad_ys is a list of tensors of the same length as ys that holds the initial gradients for each y in ys. Whengrad_ys is None, we fill in a tensor of '1's of the shape of y for each y in ys. A user can provide their own initial grad_ys to compute the derivatives using a different initial gradient for each y (e.g., if one wanted to weight the gradient differently for each value in each y).

Args:

- ys: A Tensor or list of tensors to be differentiated.
- xs: A Tensor or list of tensors to be used for differentiation.
- grad_ys: Optional. A Tensor or list of tensors the same size
 as ys and holding the gradients computed for each y in ys.
- name: Optional name to use for grouping all the gradient ops together. defaults to 'gradients'.
- colocate_gradients_with_ops: If True, try colocating gradients with the corresponding op.
- gate_gradients: If True, add a tuple around the gradients returned for an operations. This avoids some race conditions.

 aggregation_method: Specifies the method used to combine gradient terms. Accepted values are constants defined in the class AggregationMethod.

Returns:

A list of sum(dy/dx) for each x in xs.

Raises:

- LookupError: if one of the operations between x and y does not have a registered gradient function.
- ValueError: if the arguments are invalid.

class tf.AggregationMethod

A class listing aggregation methods used to combine gradients.

Computing partial derivatives can require aggregating gradient contributions. This class lists the various methods that can be used to combine gradients in the graph:

- ADD_N: All of the gradient terms are summed as part of one operation using the "AddN" op. It has the property that all gradients must be ready before any aggregation is performed.
- DEFAULT: The system-chosen default aggregation method.

Stops gradient computation.

When executed in a graph, this op outputs its input tensor as-is.

When building ops to compute gradients, this op prevents the contribution of its inputs to be taken into account. Normally, the gradient generator adds ops to a graph to compute the derivatives of a specified 'loss' by recursively finding out inputs that contributed to its computation. If you insert this op in the graph it inputs are masked from the gradient generator. They are not taken into account for computing gradients.

This is useful any time you want to compute a value with TensorFlow but need to pretend that the value was a constant. Some examples include:

- The EM algorithm where the M-step should not involve backpropagation through the output of the E-step.
- Contrastive divergence training of Boltzmann machines where, when differentiating the energy function, the training must not backpropagate through the graph that generated the samples from the model.
- Adversarial training, where no backprop should happen through the adversarial example generation process.

Args:

- input: A Tensor.
- name: A name for the operation (optional).

Returns:

A Tensor. Has the same type as input.

Gradient Clipping

TensorFlow provides several operations that you can use to add clipping functions to your graph. You can use these functions to perform general data clipping, but they're particularly useful for handling exploding or vanishing gradients.

```
tf.clip_by_value(t, clip_value_min, clip_value_max,
name=None)
```

Clips tensor values to a specified min and max.

Given a tensor ${\tt t}$, this operation returns a tensor of the same type and shape as ${\tt t}$ with its values clipped

```
toclip_value_min and clip_value_max. Any values less
than clip_value_min are set toclip_value_min. Any values greater
than clip_value_max are set to clip_value_max.
```

Args:

- t: A Tensor.
- clip_value_min: A 0-D (scalar) Tensor. The minimum value to clip
 by.
- clip_value_max: A 0-D (scalar) Tensor. The maximum value to clip
 by.
- name: A name for the operation (optional).

Returns:

A clipped Tensor.

```
tf.clip by norm(t, clip norm, name=None)
```

Clips tensor values to a maximum L2-norm.

Given a tensor t, and a maximum clip value <code>clip_norm</code>, this operation normalizes t so that its L2-norm is less than or equal to <code>clip_norm</code>. Specifically, if the L2-norm is already less than or equal to <code>clip_norm</code>, then t is not modified. If the L2-norm is greater than <code>clip_norm</code>, then this operation returns a tensor of the same type and shape as t with its values set to:

```
t * clip norm / 12norm(t)
```

In this case, the L2-norm of the output tensor is clip_norm.

This operation is typically used to clip gradients before applying them with an optimizer.

Args:

- t: A Tensor.
- clip_norm: A 0-D (scalar) Tensor > 0. A maximum clipping value.
- name: A name for the operation (optional).

Returns:

A clipped Tensor.

```
tf.clip by average norm(t, clip norm, name=None)
```

Clips tensor values to a maximum average L2-norm.

Given a tensor t, and a maximum clip value <code>clip_norm</code>, this operation normalizes t so that its average L2-norm is less than or equal to <code>clip_norm</code>. Specifically, if the average L2-norm is already less than or equal to <code>clip_norm</code>, then t is not modified. If the average L2-norm is greater than <code>clip_norm</code>, then this operation returns a tensor of the same type and shape as t with its values set to:

t * <code>clip_norm</code> / <code>l2norm_avg(t)</code>

In this case, the average L2-norm of the output tensor is clip_norm.

This operation is typically used to clip gradients before applying them with an optimizer.

Args:

- t: A Tensor.
- clip_norm: A 0-D (scalar) Tensor > 0. A maximum clipping value.
- name: A name for the operation (optional).

Returns:

A clipped Tensor.

Clips values of multiple tensors by the ratio of the sum of their norms.

Given a tuple or list of tensors t_list, and a clipping ratio clip_norm, this operation returns a list of clipped tensors list_clipped and the global norm (global_norm) of all tensors in t_list. Optionally, if you've already computed the global norm for t_list, you can specify the global norm with use norm.

To perform the clipping, the values t list[i] are set to:

```
t_list[i] * clip_norm / max(global_norm, clip_norm)
```

where:

```
global_norm = sqrt(sum([l2norm(t)**2 for t in t_list]))
```

If $clip_norm > global_norm$ then the entries in t_list remain as they are, otherwise they're all shrunk by the global ratio.

Any of the entries of t_list that are of type None are ignored.

This is the correct way to perform gradient clipping (for example, see Pascanu et al., 2012 (pdf)).

However, it is slower than <code>clip_by_norm()</code> because all the parameters must be ready before the clipping operation can be performed.

Args:

- t_list: A tuple or list of mixed Tensors, IndexedSlices, or None.
- clip_norm: A 0-D (scalar) Tensor > 0. The clipping ratio.
- use_norm: A 0-D (scalar) Tensor of type float (optional). The global norm to use. If not provided, global_norm() is used to compute the norm.
- name: A name for the operation (optional).

Returns:

- list clipped: A list of Tensors of the same type as list t.
- global norm: A 0-D (scalar) Tensor representing the global norm.

Raises:

• TypeError: If t list is not a sequence.

```
tf.global norm(t list, name=None)
```

Computes the global norm of multiple tensors.

Given a tuple or list of tensors t_{list} , this operation returns the global norm of the elements in all tensors int_{list} . The global norm is computed as:

```
global_norm = sqrt(sum([l2norm(t)**2 for t in t_list]))
```

Any entries in t_{list} that are of type None are ignored.

Args:

- t list: A tuple or list of mixed Tensors, IndexedSlices, or None.
- name: A name for the operation (optional).

Returns:

A 0-D (scalar) Tensor of type float.

Raises:

• TypeError: If t list is not a sequence.

Decaying the learning rate

```
tf.train.exponential_decay(learning_rate, global_step,
decay steps, decay rate, staircase=False, name=None)
```

Applies exponential decay to the learning rate.

When training a model, it is often recommended to lower the learning rate as the training progresses. This function applies an exponential decay function to a provided initial learning rate. It requires

a global_step value to compute the decayed learning rate. You can just pass a TensorFlow variable that you increment at each training step.

The function returns the decayed learning rate. It is computed as:

If the argument staircase is True, then global_step

/decay_steps is an integer division and the decayed learning rate follows a staircase function.

Example: decay every 100000 steps with a base of 0.96:

```
# Passing global_step to minimize() will increment it at each
step.
optimizer.minimize(...my loss..., global step=global step)
```

Args:

- learning_rate: A scalar float32 or float64 Tensor or a Python number. The initial learning rate.
- global_step: A scalar int32 or int64 Tensor or a Python number.
 Global step to use for the decay computation. Must not be negative.
- decay_steps: A scalar int32 or int64 Tensor or a Python number.
 Must be positive. See the decay computation above.
- decay_rate: A scalar float32 or float64 Tensor or a Python number. The decay rate.
- staircase: Boolean. It True decay the learning rate at discrete intervals.
- name: String. Optional name of the operation. Defaults to 'ExponentialDecay'

Returns:

A scalar Tensor of the same type as learning_rate. The decayed learning rate.

Moving Averages

Some training algorithms, such as GradientDescent and Momentum often benefit from maintaining a moving average of variables during optimization. Using the moving averages for evaluations often improve results significantly.

```
class tf.train.ExponentialMovingAverage
```

Maintains moving averages of variables by employing an exponential decay.

When training a model, it is often beneficial to maintain moving averages of the trained parameters. Evaluations that use averaged parameters sometimes produce significantly better results than the final trained values.

The <code>apply()</code> method adds shadow copies of trained variables and add ops that maintain a moving average of the trained variables in their shadow copies. It is used when building the training model. The ops that maintain moving averages are typically run after each

training step. The average() and average_name() methods give access to the shadow variables and their names. They are useful when building an evaluation model, or when restoring a model from a checkpoint file. They help use the moving averages in place of the last trained values for evaluations.

The moving averages are computed using exponential decay. You specify the decay value when creating

the Exponential Moving Average object. The shadow variables are initialized with the same initial values as the trained variables. When you run the ops to maintain the moving averages, each shadow variable is updated with the formula:

```
shadow_variable -= (1 - decay) * (shadow_variable -
variable)
```

This is mathematically equivalent to the classic formula below, but the use of an assign_sub op (the "-=" in the formula) allows concurrent lockless updates to the variables:

```
shadow_variable = decay * shadow_variable + (1 - decay) *
variable
```

Reasonable values for decay are close to 1.0, typically in the multiple-nines range: 0.999, 0.9999, etc.

Example usage when creating a training model:

```
# Create variables.
var0 = tf.Variable(...)
var1 = tf.Variable(...)
```

```
# ... use the variables to build a training model...
# Create an op that applies the optimizer. This is what we
# would use as a training op.
opt op = opt.minimize(my loss, [var0, var1])
# Create an ExponentialMovingAverage object
ema = tf.train.ExponentialMovingAverage(decay=0.9999)
# Create the shadow variables, and add ops to maintain moving
averages
# of var0 and var1.
maintain averages op = ema.apply([var0, var1])
# Create an op that will update the moving averages after each
training
# step. This is what we will use in place of the usual training
op.
with tf.control_dependencies([opt_op]):
   training op = tf.group(maintain averages op)
...train the model by running training op...
```

There are two ways to use the moving averages for evaluations:

- Build a model that uses the shadow variables instead of the variables. For this, use the average() method which returns the shadow variable for a given variable.
- Build a model normally but load the checkpoint files to evaluate by using the shadow variable names. For this use

the average_name() method. See the <u>Saver class</u> for more information on restoring saved variables.

Example of restoring the shadow variable values:

```
# Create a Saver that loads variables from their saved shadow
values.
shadow_var0_name = ema.average_name(var0)
shadow_var1_name = ema.average_name(var1)
saver = tf.train.Saver({shadow_var0_name: var0, shadow_var1_name:
var1})
saver.restore(...checkpoint filename...)
```

```
tf.train.ExponentialMovingAverage.__init__(decay,
num updates=None, name='ExponentialMovingAverage')
```

Creates a new ExponentialMovingAverage object.

The Apply() method has to be called to create shadow variables and add ops to maintain moving averages.

The optional <code>num_updates</code> parameter allows one to tweak the decay rate dynamically. It is typical to pass the count of training steps, usually kept in a variable that is incremented at each step, in which case the decay rate is lower at the start of training. This makes moving averages move faster. If passed, the actual decay rate used is:

```
min(decay, (1 + num_updates) / (10 + num_updates))
```

Args:

- decay: Float. The decay to use.
- num_updates: Optional count of number of updates applied to variables.
- name: String. Optional prefix name to use for the name of ops added
 in Apply().

```
tf.train.ExponentialMovingAverage.apply(var list=None)
```

Maintains moving averages of variables.

var_list must be a list of <code>variable</code> or <code>Tensor</code> objects. This method creates shadow variables for all elements of <code>var_list</code>. Shadow variables for <code>variable</code> objects are initialized to the variable's initial value. They will be added to

For Tensor objects, the shadow variables are initialized to 0.

the GraphKeys.MOVING AVERAGE VARIABLES collection.

shadow variables are created with trainable=False and added to the GraphKeys.ALL_VARIABLES collection. They will be returned by calls to tf.all variables().

Returns an op that updates all shadow variables as described above.

Note that apply() can be called multiple times with different lists of variables.

Args:

 var_list: A list of Variable or Tensor objects. The variables and Tensors must be of types float32 or float64.

Returns:

An Operation that updates the moving averages.

Raises:

- TypeError: If the arguments are not all float32 or float64.
- ValueError: If the moving average of one of the variables is already being computed.

```
tf.train.ExponentialMovingAverage.average_name(var)
```

Returns the name of the Variable holding the average for var.

The typical scenario for ExponentialMovingAverage is to compute moving averages of variables during training, and restore the variables from the computed moving averages during evaluations. To restore variables, you have to know the name of the shadow variables. That name and the original variable can then be passed to a Saver() object to restore the variable from the moving average

```
value with: saver = tf.train.Saver({ema.average_name(var):
    var})
```

average_name() can be called whether or not apply() has been called.

Args:

• var: A Variable **object**.

Returns:

A string: The name of the variable that will be used or was used by the ExponentialMovingAverage classto hold the moving average of var.

tf.train.ExponentialMovingAverage.average(var)

Returns the Variable holding the average of var.

Args:

• var: A Variable object.

Returns:

A variable object or None if the moving average of var is not maintained..

```
tf.train.ExponentialMovingAverage.variables to restore()
```

Returns a map of names to Variables to restore.

If a variable has a moving average, use the moving average variable name as the restore name; otherwise, use the variable name.

For example,

```
variables_to_restore = ema.variables_to_restore()
saver = tf.train.Saver(variables_to_restore)
```

Below is an example of such mapping:

```
conv/batchnorm/gamma/ExponentialMovingAverage:
conv/batchnorm/gamma,
  conv_4/conv2d_params/ExponentialMovingAverage:
conv_4/conv2d_params,
  global step: global step
```

Returns:

A map from restore_names to variables. The restore_name can be the moving_average version of the variable name if it exist, or the original variable name.

Coordinator and QueueRunner

See <u>Threading and Queues</u> for how to use threads and queues. For documentation on the Queue API, see <u>Queues</u>.

```
class tf.train.Coordinator
```

A coordinator for threads.

This class implements a simple mechanism to coordinate the termination of a set of threads.

Usage:

```
# Create a coordinator.
coord = Coordinator()
# Start a number of threads, passing the coordinator to each of
them.
...start thread 1...(coord, ...)
...start thread N...(coord, ...)
# Wait for all the threads to terminate.
coord.join(threads)
```

Any of the threads can call <code>coord.request_stop()</code> to ask for all the threads to stop. To cooperate with the requests, each thread must check for <code>coord.should stop()</code> on a regular

```
basis. coord.should_stop() returns True as soon
as coord.request stop() has been called.
```

A typical thread running with a coordinator will do something like:

```
while not coord.should_stop():
    ...do some work...
```

Exception handling:

A thread can report an exception to the coordinator as part of the should_stop() call. The exception will be re-raised from the coord.join() call.

Thread code:

```
try:
    while not coord.should_stop():
        ...do some work...
except Exception as e:
    coord.request_stop(e)
```

Main code:

```
try:
    ...
    coord = Coordinator()
    # Start a number of threads, passing the coordinator to each of
them.
    ...start thread 1...(coord, ...)
    ...start thread N...(coord, ...)
    # Wait for all the threads to terminate.
    coord.join(threads)
except Exception as e:
    ...exception that was passed to coord.request_stop()
```

To simplify the thread implementation, the Coordinator provides a context handler <code>stop_on_exception()</code> that automatically requests a stop if an exception is raised. Using the context handler the thread code above can be written as:

```
with coord.stop_on_exception():
   while not coord.should_stop():
     ...do some work...
```

Grace period for stopping:

After a thread has called <code>coord.request_stop()</code> the other threads have a fixed time to stop, this is called the 'stop grace period' and defaults to 2 minutes. If any of the threads is still alive after the grace

period expirescoord.join() raises a RuntimeException reporting the laggards.

```
try:
    ...
    coord = Coordinator()
    # Start a number of threads, passing the coordinator to each of
them.
    ...start thread 1...(coord, ...)
    ...start thread N...(coord, ...)
    # Wait for all the threads to terminate, give them 10s grace
period
    coord.join(threads, stop_grace_period_secs=10)
except RuntimeException:
    ...one of the threads took more than 10s to stop after
request_stop()
    ...was called.
except Exception:
    ...exception that was passed to coord.request_stop()
```

```
tf.train.Coordinator.__init__()
```

Create a new Coordinator.

```
tf.train.Coordinator.clear_stop()
```

Clears the stop flag.

After this is called, calls to should_stop() will return False.

```
tf.train.Coordinator.join(threads,
stop_grace_period_secs=120)
```

Wait for threads to terminate.

Blocks until all threads have terminated or request_stop() is called.

After the threads stop, if an exc_info was passed to request_stop, that exception is re-raised.

Grace period handling: When request_stop() is called, threads are given 'stop_grace_period_secs' seconds to terminate. If any of them is still alive after that period expires, a RuntimeError is raised. Note that if anexc_info was passed to request_stop() then it is raised instead of that RuntimeError.

Args:

- threads: List of threading. Threads. The started threads to join.
- stop_grace_period_secs: Number of seconds given to threads to
 stop after request stop() has been called.

Raises:

 RuntimeError: If any thread is still alive after request_stop() is called and the grace period expires.

```
tf.train.Coordinator.request stop(ex=None)
```

Request that the threads stop.

After this is called, calls to should stop() will return True.

Args:

ex: Optional Exception, or Python exc_info tuple as returned
 by sys.exc_info(). If this is the first call to request_stop() the
 corresponding exception is recorded and re-raised from join().

```
tf.train.Coordinator.should stop()
```

Check if stop was requested.

Returns:

True if a stop was requested.

```
tf.train.Coordinator.stop on exception()
```

Context manager to request stop when an Exception is raised.

Code that uses a coordinator must catch exceptions and pass them to the request_stop() method to stop the other threads managed by the coordinator.

This context handler simplifies the exception handling. Use it as follows:

```
with coord.stop_on_exception():
    # Any exception raised in the body of the with
    # clause is reported to the coordinator before terminating
    # the execution of the body.
...body...
```

This is completely equivalent to the slightly longer code:

```
try:
    ...body...
exception Exception as ex:
    coord.request_stop(ex)
```

Yields:

nothing.

```
tf.train.Coordinator.wait for stop(timeout=None)
```

Wait till the Coordinator is told to stop.

Args:

 timeout: Float. Sleep for up to that many seconds waiting for should_stop() to become True.

Returns:

True if the Coordinator is told stop, False if the timeout expired.

```
class tf.train.QueueRunner
```

Holds a list of enqueue operations for a queue, each to be run in a thread.

Queues are a convenient TensorFlow mechanism to compute tensors asynchronously using multiple threads. For example in the canonical 'Input Reader' setup one set of threads generates filenames in a queue; a second set of threads read records from the files, processes them, and enqueues tensors on a second queue; a third set of threads dequeues these input records to construct batches and runs them through training operations.

There are several delicate issues when running multiple threads that way: closing the queues in sequence as the input is exhausted, correctly catching and reporting exceptions, etc.

The QueueRunner, combined with the Coordinator, helps handle these issues.

```
tf.train.QueueRunner.__init__(queue=None,
enqueue_ops=None, close_op=None, cancel_op=None,
queue runner def=None)
```

Create a QueueRunner.

On construction the QueueRunner adds an op to close the queue.

That op will be run if the enqueue ops raise exceptions.

When you later call the create_threads() method,

the QueueRunner will create one thread for each op inenqueue_ops.

Each thread will run its enqueue op in parallel with the other threads. The enqueue ops do not have to all be the same op, but it is expected that they all enqueue tensors in queue.

Args:

- queue: A Queue.
- enqueue ops: List of enqueue ops to run in threads later.
- close_op: Op to close the queue. Pending enqueue ops are preserved.
- cancel_op: Op to close the queue and cancel pending enqueue ops.

 queue_runner_def: Optional QueueRunnerDef protocol buffer. If specified, recreates the QueueRunner from its contents. queue_runner_def and the other arguments are mutually exclusive.

Raises:

- ValueError: If both queue_runner_def and queue are both specified.
- ValueError: If queue or enqueue_ops are not provided when not restoring from queue_runner_def.

```
tf.train.QueueRunner.cancel_op
```

```
tf.train.QueueRunner.close op
```

tf.train.QueueRunner.create_threads(sess, coord=None,
daemon=False, start=False)

Create threads to run the enqueue ops.

This method requires a session in which the graph was launched. It creates a list of threads, optionally starting them. There is one thread for each op passed in enqueue ops.

The coord argument is an optional coordinator, that the threads will use to terminate together and report exceptions. If a coordinator is given, this method starts an additional thread to close the queue when the coordinator requests a stop.

This method may be called again as long as all threads from a previous call have stopped.

Args:

- sess: A Session.
- coord: Optional Coordinator object for reporting errors and checking stop conditions.
- daemon: Boolean. If True make the threads daemon threads.
- start: Boolean. If True starts the threads. If False the caller must call the start() method of the returned threads.

Returns:

A list of threads.

Raises:

RuntimeError: If threads from a previous call

to create_threads() are still running.

tf.train.QueueRunner.enqueue_ops

tf.train.QueueRunner.exceptions raised

Exceptions raised but not handled by the QueueRunner threads.

Exceptions raised in queue runner threads are handled in one of two ways depending on whether or not accordinator was passed to create threads():

- With a Coordinator, exceptions are reported to the coordinator and forgotten by the QueueRunner.
- Without a Coordinator, exceptions are captured by the QueueRunner and made available in thisexceptions_raised property.

Returns:

A list of Python Exception objects. The list is empty if no exception was captured. (No exceptions are captured when using a Coordinator.)

tf.train.QueueRunner.from_proto(queue_runner_def)

tf.train.QueueRunner.name

The string name of the underlying Queue.

```
tf.train.QueueRunner.to proto()
```

Converts this QueueRunner to a QueueRunnerDef protocol buffer.

Returns:

A QueueRunnerDef protocol buffer.

```
tf.train.add_queue_runner(qr, collection='queue_runners')
Adds a QueueRunner to a collection in the graph.
```

When building a complex model that uses many queues it is often difficult to gather all the queue runners that need to be run. This convenience function allows you to add a queue runner to a well known collection in the graph.

The companion method start_queue_runners() can be used to start threads for all the collected queue runners.

Args:

- qr: A QueueRunner.
- collection: A Graphkey specifying the graph collection to add the queue runner to. Defaults to Graphkeys. QUEUE RUNNERS.

```
tf.train.start_queue_runners(sess=None, coord=None,
daemon=True, start=True, collection='queue runners')
```

Starts all queue runners collected in the graph.

This is a companion method to <code>add_queue_runner()</code>. It just starts threads for all queue runners collected in the graph. It returns the list of all threads.

Args:

- sess: Session used to run the queue ops. Defaults to the default session.
- coord: Optional Coordinator for coordinating the started threads.
- daemon: Whether the threads should be marked as daemons,
 meaning they don't block program exit.
- start: Set to False to only create the threads, not start them.
- collection: A Graphkey specifying the graph collection to get the queue runners from. Defaults to Graphkeys.QUEUE_RUNNERS.

Returns:

A list of threads.

Summary Operations

The following ops output Summary protocol buffers as serialized string tensors.

You can fetch the output of a summary op in a session, and pass it to a <u>SummaryWriter</u> to append it to an event file. Event files contain <u>Event</u> protos that can contain <u>Summary</u> protos along with the

timestamp and step. You can then use TensorBoard to visualize the

contents of the event files. See <u>TensorBoard and Summaries</u> for more details.

```
tf.scalar_summary(tags, values, collections=None,
name=None)
```

Outputs a Summary protocol buffer with scalar values.

The input tags and values must have the same shape. The generated summary has a summary value for each tag-value pair in tags and values.

Args:

- tags: A string Tensor. Tags for the summaries.
- values: A real numeric Tensor. Values for the summaries.
- collections: Optional list of graph collections keys. The new summary op is added to these collections. Defaults
 to [GraphKeys.SUMMARIES].
- name: A name for the operation (optional).

Returns:

A scalar Tensor of type string. The serialized Summary protocol buffer.

```
tf.image_summary(tag, tensor, max_images=3,
collections=None, name=None)
```

Outputs a summary protocol buffer with images.

The summary has up to max_images summary values containing images. The images are built from tensorwhich must be 4-D with shape [batch_size, height, width, channels] and where channels can be:

- 1: tensor is interpreted as Grayscale.
- 3: tensor is interpreted as RGB.
- 4: tensor is interpreted as RGBA.

The images have the same number of channels as the input tensor. For float input, the values are normalized one image at a time to fit in the range [0, 255]. uint8 values are unchanged. The op uses two different normalization algorithms:

- If the input values are all positive, they are rescaled so the largest one is 255.
- If any input value is negative, the values are shifted so input value 0.0 is at 127. They are then rescaled so that either the smallest value is 0, or the largest one is 255.

The tag argument is a scalar Tensor of type string. It is used to build the tag of the summary values:

- If max_images is 1, the summary value tag is '*tag*/image'.
- If max_images is greater than 1, the summary value tags are generated sequentially as '*tag*/image/0', '*tag*/image/1', etc.

- tag: A scalar Tensor of type string. Used to build the tag of the summary values.
- tensor: A 4-D uint8 or float32 Tensor of shape [batch_size, height, width, channels] where channels is 1, 3, or 4.
- max_images: Max number of batch elements to generate images for.
- collections: Optional list of ops.GraphKeys. The collections to add the summary to. Defaults to [ops.GraphKeys.SUMMARIES]
- name: A name for the operation (optional).

A scalar Tensor of type string. The serialized Summary protocol buffer.

tf.histogram_summary(tag, values, collections=None,
name=None)

Outputs a summary protocol buffer with a histogram.

The generated Summary has one summary value containing a
histogram for values.

This op reports an OutOfRange error if any value is not finite.

- tag: A string Tensor. 0-D. Tag to use for the summary value.
- values: A real numeric Tensor. Any shape. Values to use to build the histogram.

- collections: Optional list of graph collections keys. The new summary op is added to these collections. Defaults
 to [GraphKeys.SUMMARIES].
- name: A name for the operation (optional).

A scalar Tensor of type string. The serialized Summary protocol buffer.

```
tf.nn.zero fraction(value, name=None)
```

Returns the fraction of zeros in value.

If value is empty, the result is nan.

This is useful in summaries to measure and report sparsity. For example,

```
z = tf.Relu(...)
summ = tf.scalar_summary('sparsity', tf.zero_fraction(z))
```

Args:

- value: A tensor of numeric type.
- name: A name for the operation (optional).

Returns:

The fraction of zeros in value, with type float32.

```
tf.merge summary(inputs, collections=None, name=None)
```

Merges summaries.

This op creates a <u>Summary</u> protocol buffer that contains the union of all the values in the input summaries.

When the Op is run, it reports an InvalidArgument error if multiple values in the summaries to merge use the same tag.

Args:

- inputs: A list of string Tensor objects containing serialized Summary protocol buffers.
- collections: Optional list of graph collections keys. The new summary op is added to these collections. Defaults
 to [GraphKeys.SUMMARIES].
- name: A name for the operation (optional).

Returns:

A scalar Tensor of type string. The serialized Summary protocol buffer resulting from the merging.

```
tf.merge all summaries(key='summaries')
```

Merges all summaries collected in the default graph.

Args:

key: GraphKey used to collect the summaries. Defaults

to GraphKeys.SUMMARIES.

Returns:

If no summaries were collected, returns None. Otherwise returns a scalar Tensor of typestring containing the

serialized summary protocol buffer resulting from the merging.

Adding Summaries to Event Files

See <u>Summaries and TensorBoard</u> for an overview of summaries, event files, and visualization in TensorBoard.

class tf.train.SummaryWriter

Writes Summary protocol buffers to event files.

The SummaryWriter class provides a mechanism to create an event file in a given directory and add summaries and events to it. The class updates the file contents asynchronously. This allows a training program to call methods to add data to the file directly from the training loop, without slowing down training.

```
tf.train.SummaryWriter.__init__(logdir, graph_def=None,
max queue=10, flush secs=120)
```

Creates a SummaryWriter and an event file.

On construction the summary writer creates a new event file in logdir. This event file will contain Eventprotocol buffers constructed when you call one of the following

If you pass a graph_def protocol buffer to the constructor it is added to the event file. (This is equivalent to calling add graph() later).

TensorBoard will pick the graph from the file and display it graphically so you can interactively explore the graph you built. You will usually pass the graph from the session in which you launched it:

```
...create a graph...
# Launch the graph in a session.
sess = tf.Session()
# Create a summary writer, add the 'graph_def' to the event file.
writer = tf.train.SummaryWriter(<some-directory>, sess.graph def)
```

The other arguments to the constructor control the asynchronous writes to the event file:

- flush_secs: How often, in seconds, to flush the added summaries and events to disk.
- max_queue: Maximum number of summaries or events pending to be written to disk before one of the 'add' calls block.

- logdir: A string. Directory where event file will be written.
- graph_def: A GraphDef protocol buffer.
- max_queue: Integer. Size of the queue for pending events and summaries.

 flush_secs: Number. How often, in seconds, to flush the pending events and summaries to disk.

```
tf.train.SummaryWriter.add_summary(summary,
global step=None)
```

Adds a Summary protocol buffer to the event file.

This method wraps the provided summary in an Event protocol buffer and adds it to the event file.

You can pass the result of evaluating any summary op, using [Session.run()](client.md#Session.run] or Tensor.eval(), to this

function. Alternatively, you can pass a tf.Summary protocol buffer that you populate with your own data. The latter is commonly done to report evaluation results in event files.

Args:

- summary: A Summary protocol buffer, optionally serialized as a string.
- global_step: Number. Optional global step value to record with the summary.

```
tf.train.SummaryWriter.add_session_log(session_log,
global step=None)
```

Adds a SessionLog protocol buffer to the event file.

This method wraps the provided session in an Event procotol buffer and adds it to the event file.

Args:

- session log: A SessionLog protocol buffer.
- global_step: Number. Optional global step value to record with the summary.

```
tf.train.SummaryWriter.add event(event)
```

Adds an event to the event file.

Args:

event: An Event protocol buffer.

```
tf.train.SummaryWriter.add_graph(graph_def,
global_step=None)
```

Adds a GraphDef protocol buffer to the event file.

The graph described by the protocol buffer will be displayed by TensorBoard. Most users pass a graph in the constructor instead.

- graph def: A GraphDef protocol buffer.
- global_step: Number. Optional global step counter to record with the graph.

```
tf.train.SummaryWriter.flush()
```

Flushes the event file to disk.

Call this method to make sure that all pending events have been written to disk.

```
tf.train.SummaryWriter.close()
```

Flushes the event file to disk and close the file.

Call this method when you do not need the summary writer anymore.

```
tf.train.summary_iterator(path)
```

An iterator for reading Event protocol buffers from an event file. You can use this function to read events written to an event file. It returns a Python iterator that yields Eventprotocol buffers.

Example: Print the contents of an events file.

```
for e in tf.train.summary_iterator(path to events file):
    print(e)
```

Example: Print selected summary values.

```
# This example supposes that the events file contains summaries
with a
# summary value tag 'loss'. These could have been added by
calling
# `add_summary()`, passing the output of a scalar summary op
created with
# with: `tf.scalar_summary(['loss'], loss_tensor)`.
for e in tf.train.summary_iterator(path to events file):
    for v in e.summary.value:
        if v.tag == 'loss':
```

```
print(v.simple value)
```

See the protocol buffer definitions of **Event** and **Summary** for more information about their attributes.

Args:

• path: The path to an event file created by a SummaryWriter.

Yields:

Event protocol buffers.

Training utilities

```
tf.train.global step(sess, global step tensor)
```

Small helper to get the global step.

```
# Creates a variable to hold the global_step.
global_step_tensor = tf.Variable(10, trainable=False,
name='global_step')
# Creates a session.
sess = tf.Session()
# Initializes the variable.
sess.run(global_step_tensor.initializer)
print('global_step: %s' % tf.train.global_step(sess,
global_step_tensor))
global_step: 10
```

Args:

• sess: A brain Session object.

 global_step_tensor: Tensor or the name of the operation that contains the global step.

Returns:

The global step value.

```
tf.train.write_graph(graph_def, logdir, name,
as_text=True)
```

Writes a graph proto on disk.

The graph is written as a binary proto unless as text is True.

```
v = tf.Variable(0, name='my_variable')
sess = tf.Session()
tf.train.write_graph(sess.graph_def, '/tmp/my-model',
'train.pbtxt')
```

Args:

- graph def: A GraphDef protocol buffer.
- logdir: Directory where to write the graph.
- name: Filename for the graph.
- as_text: If True, writes the graph as an ASCII proto.

Other Functions and Classes

```
class tf.train.LooperThread
```

A thread that runs code repeatedly, optionally on a timer.

This thread class is intended to be used with a Coordinator. It repeatedly runs code specified either as targetand args or by the run loop() method.

Before each run the thread checks if the coordinator has requested stop. In that case the looper thread terminates immediately.

If the code being run raises an exception, that exception is reported to the coordinator and the thread terminates. The coordinator will then request all the other threads it coordinates to stop.

You typically pass looper threads to the supervisor Join () method.

```
tf.train.LooperThread.__init__(coord,
timer_interval_secs, target=None, args=None)
```

Create a LooperThread.

Args:

- coord: A Coordinator.
- timer_interval_secs: Time boundaries at which to call Run(), or
 None if it should be called back to back.
- target: Optional callable object that will be executed in the thread.
- args: Optional arguments to pass to target when calling it.

Raises:

• ValueError: If one of the arguments is invalid.

tf.train.LooperThread.daemon

A boolean value indicating whether this thread is a daemon thread (True) or not (False).

This must be set before start() is called, otherwise RuntimeError is raised. Its initial value is inherited from the creating thread; the main thread is not a daemon thread and therefore all threads created in the main thread default to daemon = False.

The entire Python program exits when no alive non-daemon threads are left.

tf.train.LooperThread.getName()

tf.train.LooperThread.ident

Thread identifier of this thread or None if it has not been started.

This is a nonzero integer. See the thread.get_ident() function. Thread identifiers may be recycled when a thread exits and another thread is created. The identifier is available even after the thread has exited.

tf.train.LooperThread.isAlive()

Return whether the thread is alive.

This method returns True just before the run() method starts until just after the run() method terminates. The module function enumerate() returns a list of all alive threads.

```
tf.train.LooperThread.isDaemon()
```

```
tf.train.LooperThread.is_alive()
```

Return whether the thread is alive.

This method returns True just before the run() method starts until just after the run() method terminates. The module function enumerate() returns a list of all alive threads.

```
tf.train.LooperThread.join(timeout=None)
```

Wait until the thread terminates.

This blocks the calling thread until the thread whose join() method is called terminates -- either normally or through an unhandled exception or until the optional timeout occurs.

When the timeout argument is present and not None, it should be a floating point number specifying a timeout for the operation in seconds (or fractions thereof). As join() always returns None, you must call isAlive() after join() to decide whether a timeout happened - if the thread is still alive, the join() call timed out.

When the timeout argument is not present or None, the operation will block until the thread terminates.

A thread can be join()ed many times.

join() raises a RuntimeError if an attempt is made to join the current thread as that would cause a deadlock. It is also an error to join() a thread before it has been started and attempts to do so raises the same exception.

```
tf.train.LooperThread.loop(coord, timer_interval_secs,
target, args=None)
```

Start a LooperThread that calls a function periodically.

```
If timer_interval_secs is None the thread

calls target(args) repeatedly. Otherwise target(args) is called

every timer_interval_secs seconds. The thread terminates when a

stop of the coordinator is requested.
```

Args:

- coord: A Coordinator.
- timer_interval_secs: Number. Time boundaries at which to call target.
- target: A callable object.
- args: Optional arguments to pass to target when calling it.

Returns:

The started thread.

```
tf.train.LooperThread.name
```

A string used for identification purposes only.

It has no semantics. Multiple threads may be given the same name. The initial name is set by the constructor.

```
tf.train.LooperThread.run()
```

```
tf.train.LooperThread.run loop()
```

Called at 'timer_interval_secs' boundaries.

```
tf.train.LooperThread.setDaemon(daemonic)
```

```
tf.train.LooperThread.setName(name)
```

```
tf.train.LooperThread.start()
```

Start the thread's activity.

It must be called at most once per thread object. It arranges for the object's run() method to be invoked in a separate thread of control.

This method will raise a RuntimeError if called more than once on the same thread object.

```
tf.train.LooperThread.start_loop()
```

Called when the thread starts.

```
tf.train.export_meta_graph(filename=None,
meta_info_def=None, graph_def=None, saver_def=None,
collection_list=None, as_text=False)
```

Returns MetaGraphDef proto. Optionally writes it to filename.

This function exports the graph, saver, and collection objects into MetaGraphDef protocol buffer with the intension of it being imported at a later time or location to restart training, run inference, or be a subgraph.

- filename: Optional filename including the path for writing the generated MetaGraphDef protocol buffer.
- meta_info_def: MetaInfoDef protocol buffer.
- graph_def: GraphDef protocol buffer.
- saver_def: SaverDef protocol buffer.
- collection_list: List of string keys to collect.
- as_text: If True, writes the MetaGraphDef as an ASCII proto.

A MetaGraphDef proto.

```
tf.train.generate_checkpoint_state_proto(save_dir,
model_checkpoint_path, all_model_checkpoint_paths=None)
```

Generates a checkpoint state proto.

Args:

- save_dir: Directory where the model was saved.
- model checkpoint path: The checkpoint file.
- all_model_checkpoint_paths: List of strings. Paths to all not-yetdeleted checkpoints, sorted from oldest to newest. If this is a nonempty list, the last element must be equal to model_checkpoint_path. These paths are also saved in the CheckpointState proto.

Returns:

CheckpointState proto with model_checkpoint_path and all_model_checkpoint_paths updated to either absolute paths or relative paths to the current save_dir.

```
tf.train.import meta graph(meta graph or file)
```

Recreates a Graph saved in a MetaGraphDef proto.

This function reads from a file containing a MetaGraphDef proto, adds all the nodes from the graph_def proto to the current graph, recreates all the collections, and returns a saver from saver_def.

In combination with $export_meta_graph()$, this function can be used to

- Serialize a graph along with other Python objects such as QueueRunner, Variable into aMetaGraphDef.
- Restart training from a saved graph and checkpoints.
- · Run inference from a saved graph and checkpoints.

Args:

meta_graph_or_file: MetaGraphDef protocol buffer or filename
 (including the path) containing aMetaGraphDef.

Returns:

A saver constructed rom saver_def in MetaGraphDef.

Wraps python functions

Note: Functions taking Tensor arguments can also take anything accepted by tf.convert to tensor.

Contents

- Wraps python functions
- Script Language Operators.
- Other Functions and Classes
- tf.py func(func, inp, Tout, name=None)

Script Language Operators.

TensorFlow provides allows you to wrap python/numpy functions as TensorFlow operators.

Other Functions and Classes

```
tf.py_func(func, inp, Tout, name=None)
```

Wraps a python function and uses it as a tensorflow op.

Given a python function func, which takes numpy arrays as its inputs and returns numpy arrays as its outputs. E.g.,

def my_func(x): return np.sinh(x) inp = tf.placeholder(..., tf.float32) y = py_func(my_func, [inp], [tf.float32])

The above snippet constructs a tf graph which invokes a numpy sinh(x) as an op in the graph.

Args:

- func: A python function.
- inp: A list of Tensor.
- Tout: A list of tensorflow data types indicating what func returns.
- name: A name for the operation (optional).

Returns:

A list of Tensor which func computes.

Testing

Contents

```
Testing
Unit tests
tf.test.main()
Utilities
tf.test.assert_equal_graph_def(actual, expected)
tf.test.get_temp_dir()
tf.test.is_built_with_cuda()
```

- Gradient checking
- tf.test.compute_gradient(x, x_shape, y, y_shape, x init value=None, delta=0.001, init targets=None)
- tf.test.compute_gradient_error(x, x_shape, y, y_shape, x init value=None, delta=0.001, init targets=None)

Unit tests

TensorFlow provides a convenience class inheriting from unittest. TestCase which adds methods relevant to

TensorFlow tests. Here is an example:

```
import tensorflow as tf

class SquareTest(tf.test.TestCase):

   def testSquare(self):
        with self.test_session():
        x = tf.square([2, 3])
        self.assertAllEqual(x.eval(), [4, 9])

if __name__ == '__main__':
    tf.test.main()
```

tf.test.TestCase inherits from unittest.TestCase but adds a few additional methods. We will document these methods soon.

Runs all unit tests.

Utilities

```
tf.test.assert equal graph def(actual, expected)
```

Asserts that two GraphDefs are (mostly) the same.

Compares two <code>GraphDef</code> protos for equality, ignoring versions and ordering of nodes, attrs, and control inputs. Node names are used to match up nodes between the graphs, so the naming of nodes must be consistent.

Args:

- actual: The GraphDef we have.
- expected: The GraphDef we expected.

Raises:

- AssertionError: If the GraphDefs do not match.
- TypeError: If either argument is not a GraphDef.

```
tf.test.get temp dir()
```

Returns a temporary directory for use during tests.

There is no need to delete the directory after the test.

The temporary directory.

```
tf.test.is built with cuda()
```

Returns whether TensorFlow was built with CUDA (GPU) support.

Gradient checking

```
compute gradient and compute gradient error perform
```

numerical differentiation of graphs for comparison against registered analytic gradients.

```
tf.test.compute_gradient(x, x_shape, y, y_shape,
x_init_value=None, delta=0.001, init_targets=None)
```

Computes and returns the theoretical and numerical Jacobian.

- x: a tensor or list of tensors
- x_shape: the dimensions of x as a tuple or an array of ints. If x is a
 list, then this is the list of shapes.
- y: a tensor
- y_shape: the dimensions of y as a tuple or an array of ints.
- x_init_value: (optional) a numpy array of the same shape as "x"
 representing the initial value of x. If x is a list, this should be a list of

numpy arrays. If this is none, the function will pick a random tensor as the initial value.

- delta: (optional) the amount of perturbation.
- init_targets: list of targets to run to initialize model params.

TODO(mrry): remove this argument.

Returns:

Two 2-d numpy arrays representing the theoretical and numerical Jacobian for dy/dx. Each has "x_size" rows and "y_size" columns where "x_size" is the number of elements in x and "y_size" is the number of elements in y. If x is a list, returns a list of two numpy arrays.

```
tf.test.compute_gradient_error(x, x_shape, y, y_shape,
x init value=None, delta=0.001, init targets=None)
```

Computes the gradient error.

Computes the maximum error for dy/dx between the computed Jacobian and the numerically estimated Jacobian.

This function will modify the tensors passed in as it adds more operations and hence changing the consumers of the operations of the input tensors.

This function adds operations to the current session. To compute the error using a particular device, such as a GPU, use the standard methods for setting a device (e.g. using with sess.graph.device() or setting a device function in the session constructor).

Args:

x: a tensor or list of tensors

- x_shape: the dimensions of x as a tuple or an array of ints. If x is a
 list, then this is the list of shapes.
- y: a tensor
- y shape: the dimensions of y as a tuple or an array of ints.
- x_init_value: (optional) a numpy array of the same shape as "x" representing the initial value of x. If x is a list, this should be a list of numpy arrays. If this is none, the function will pick a random tensor as the initial value.
- delta: (optional) the amount of perturbation.
- init_targets: list of targets to run to initialize model params.
 TODO(mrry): Remove this argument.

The maximum error in between the two Jacobians.

- tf.contrib.layers.assert_same_float_dtype(tensors=None, dtype=None)

Ops for building neural network layers, regularizers, summaries, etc.

Higher level ops for building neural network layers.

This package provides several ops that take care of creating variables that are used internally in a consistent way and provide the building blocks for many common machine learning algorithms.

```
tf.contrib.layers.convolution2d(x, num_output_channels,
kernel_size, activation_fn=None, stride=(1, 1),
padding='SAME', weight_init=_initializer,
bias_init=_initializer, name=None,
weight_collections=None, bias_collections=None,
output_collections=None, weight_regularizer=None,
bias_regularizer=None)
```

Adds the parameters for a conv2d layer and returns the output.

A neural network convolution layer is generally defined as: y=f(conv2d(w,x)+b)y=f(conv2d(w,x)+b) where f is given byactivation_fn, conv2d is tf.nn.conv2d and x has shape [batch, height, width, channels]. The output of this op is of shape [batch, out_height, out_width, num_output_channels], whereout_width and out_height are determined by the padding argument. See conv2D for details.

This op creates w and optionally b and adds various summaries that can be useful for visualizing learning or diagnosing training problems. Bias can be disabled by setting bias init to None.

The variable creation is compatible with tf.variable_scope and so can be reused withtf.variable_scope or tf.make_template.

Most of the details of variable creation can be controlled by specifying the initializers (weight_init andbias_init) and which collections to place the created variables in (weight_collections andbias_collections).

A per layer regularization can be specified by setting weight_regularizer. This is only applied to weights and not the bias.

- x: A 4-D input Tensor.
- num_output_channels: The number of output channels (i.e. the size
 of the last dimension of the output).
- kernel_size: A length 2 list or tuple containing the kernel size.

- activation_fn: A function that requires a single Tensor that is applied as a non-linearity.
- stride: A length 2 list or tuple specifying the stride of the sliding window across the image.
- padding: A string from: "SAME", "VALID". The type of padding algorithm to use.
- weight_init: An optional initialization. If not specified, uses Xavier initialization (seetf.learn.xavier initializer).
- bias_init: An initializer for the bias, defaults to 0. Set toNone in order to disable bias.
- name: The name for this operation is used to name operations and to find variables. If specified it must be unique for this scope, otherwise a unique name starting with "convolution2d" will be created.
 Seetf.variable op scope for details.
- weight_collections: List of graph collections to which weights are added.
- bias_collections: List of graph collections to which biases are added.
- output_collections: List of graph collections to which outputs are added.
- weight_regularizer: A regularizer like the result
 of 11_regularizer or 12_regularizer. Used for weights.
- bias_regularizer: A regularizer like the result
 of 11 regularizer or 12 regularizer. Used for biases.

The result of applying a 2-D convolutional layer.

Raises:

• ValueError: If kernel size or stride are not length 2.

```
tf.contrib.layers.fully_connected(x, num_output_units,
activation_fn=None, weight_init=_initializer,
bias_init=_initializer, name=None,
weight_collections=('weights',),
bias_collections=('biases',),
output_collections=('activations',),
weight_regularizer=None, bias_regularizer=None)
```

Adds the parameters for a fully connected layer and returns the output.

A fully connected layer is generally defined as a matrix multiply: y =

```
f(w * x + b) where f is given by activation_fn.
```

If activation fn is None, the result of y = w * x + b is returned.

This op creates w and optionally b. Bias (b) can be disabled by setting bias init to None.

The variable creation is compatible with tf.variable_scope and so

can be reused with tf. variable scope or tf. make template.

Most of the details of variable creation can be controlled by specifying the initializers (weight_init andbias_init) and which in collections to place the created variables

(weight_collections andbias_collections; note that the

variables are always added to the VARIABLES collection). The output of the layer can be placed in custom collections

using output_collections. The collections arguments default toweights, beases and activations, respectively.

A per layer regularization can be specified by setting weight_regularizer and bias_regularizer, which are applied to the weights and biases respectively, and whose output is added to the REGULARIZATION LOSSES collection.

- x: The input Tensor.
- num output units: The size of the output.
- activation_fn: A function that requires a single Tensor that is applied as a non-linearity. If None is used, do not apply any activation.
- weight_init: An optional weight initialization, defaults
 to xavier_initializer.
- bias_init: An initializer for the bias, defaults to 0. Set to None in order to disable bias.
- name: The name for this operation is used to name operations and to find variables. If specified it must be unique for this scope, otherwise a unique name starting with "fully_connected" will be created.
 Seetf.variable op scope for details.
- weight_collections: List of graph collections to which weights are added.
- bias_collections: List of graph collections to which biases are added.
- output_collections: List of graph collections to which outputs are added.

- weight_regularizer: A regularizer like the result
 of 11 regularizer or 12 regularizer. Used for weights.
- bias_regularizer: A regularizer like the result
 of 11 regularizer or 12 regularizer. Used for biases.

The output of the fully connected layer.

Aliases for fully_connected which set a default activation function are available: relu, relu6 and linear.

Regularizers

Regularization can help prevent overfitting. These have the signature fn (weights). The loss is typically added

to tf.GraphKeys.REGULARIZATION LOSS

```
tf.contrib.layers.l1 regularizer(scale)
```

Returns a function that can be used to apply L1 regularization to weights.

L1 regularization encourages sparsity.

Args:

scale: A scalar multiplier Tensor. 0.0 disables the regularizer.

A function with signature 11 (weights, name=None) that apply L1 regularization.

Raises:

ValueError: If scale is outside of the range [0.0, 1.0] or if scale is not
a float.

```
tf.contrib.layers.12 regularizer(scale)
```

Returns a function that can be used to apply L2 regularization to weights.

Small values of L2 can help prevent overfitting the training data.

Args:

• scale: A scalar multiplier Tensor. 0.0 disables the regularizer.

Returns:

A function with signature 12 (weights, name=None) that applies L2 regularization.

Raises:

ValueError: If scale is outside of the range [0.0, 1.0] or if scale is not
a float.

Initializers

Initializers are used to initialize variables with sensible values given their size, data type, and purpose.

```
tf.contrib.layers.xavier_initializer(uniform=True,
seed=None, dtype=tf.float32)
```

Returns an initializer performing "Xavier" initialization for weights.

This function implements the weight initialization from:

Xavier Glorot and Yoshua Bengio (2010): Understanding the difficulty of training deep feedforward neural networks. International conference on artificial intelligence and statistics.

This initializer is designed to keep the scale of the gradients roughly the same in all layers. In uniform distribution this ends up being the

```
range: x = sqrt(6. / (in + out)); [-x, x] and for normal
```

distribution a standard deviation of sqrt(3. / (in + out)) is used.

The returned initializer assumes that the shape of the weight matrix to be initialized is [in, out].

Args:

- uniform: Whether to use uniform or normal distributed random initialization.
- seed: A Python integer. Used to create random seeds.

```
See set random seed for behavior.
```

dtype: The data type. Only floating point types are supported.

An initializer for a 2-D weight matrix.

Raises:

TypeError: If dtype is not a floating point type.

```
tf.contrib.layers.xavier_initializer_conv2d(uniform=True,
seed=None, dtype=tf.float32)
```

Returns an "Xavier" initializer for 2D convolution weights.

For details on the initialization performed, see xavier initializer.

This function initializes a convolution weight variable which is assumed to be 4-D. The first two dimensions are expected to be the kernel size, the third dimension is the number of input channels, and the last dimension is the number of output channels.

The number of inputs is therefore shape[0]*shape[1]*shape[2],

and the number of outputs is shape [0] * shape [1] * shape [3].

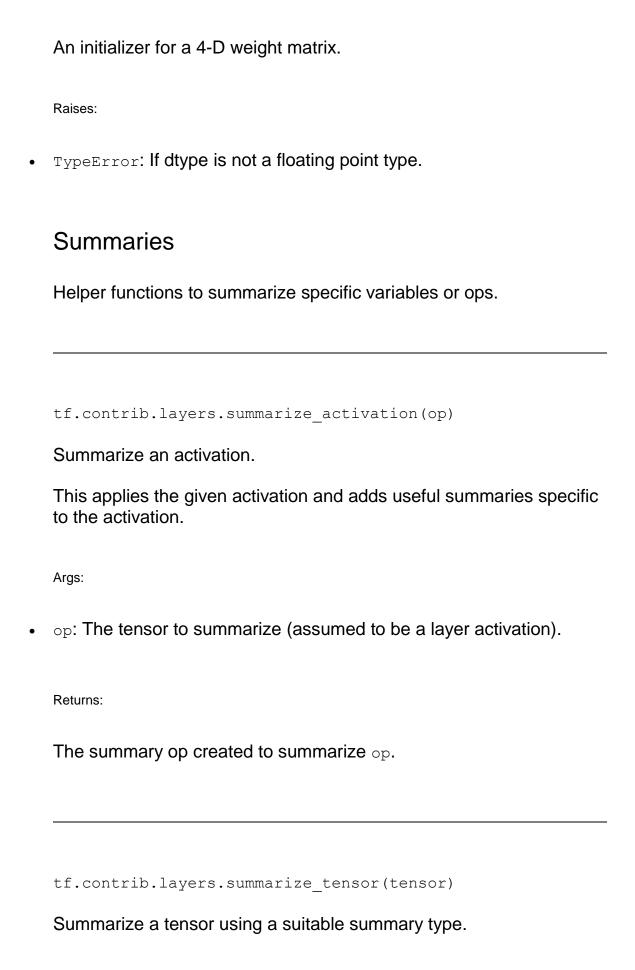

Args:

- uniform: Whether to use uniform or normal distributed random initialization.
- seed: A Python integer. Used to create random seeds.

See set_random_seed for behavior.

• dtype: The data type. Only floating point types are supported.

Returns:

This function adds a summary op for tensor. The type of summary depends on the shape of tensor. For scalars, a scalar_summary is created, for all other tensors, histogram summary is used.

Args:

tensor: The tensor to summarize

Returns:

The summary op created.

```
tf.contrib.layers.summarize_tensors(tensors,
summarizer=summarize tensor)
```

Summarize a set of tensors.

```
tf.contrib.layers.summarize_collection(collection,
name_filter=None, summarizer=summarize_tensor)
```

Summarize a graph collection of tensors, possibly filtered by name.

The layers module defines convenience

```
functions summarize_variables, summarize_weights and summariz
e biases, which set the collection argument
```

of summarize_collection to VARIABLES, WEIGHTS and BIASES, respectively.

tf.contrib.layers.summarize_activations(name_filter=None,
summarizer=summarize activation)

Summarize activations, using summarize activation to summarize.

Other Functions and Classes

tf.contrib.layers.assert_same_float_dtype(tensors=None,
dtype=None)

Validate and return float type based on tensors and dtype.

For ops such as matrix multiplication, inputs and weights must be of the same float type. This function validates that all tensors are the same type, validates that type is dtype (if supplied), and returns the type. Type must bedtypes.float32 or dtypes.float64. If neither tensors nor dtype is supplied, default todtypes.float32.

Args:

- tensors: Tensors of input values. Can include None elements, which will be ignored.
- dtype: Expected type.

Returns:

Validated type.

Raises:

 ValueError: if neither tensors nor dtype is supplied, or result is not float.

Utilities (contrib)

Contents

- <u>Utilities (contrib)</u>
- Miscellaneous Utility Functions
- tf.contrib.util.constant value(tensor)
- tf.contrib.util.make_tensor_proto(values, dtype=None, shape=None)

Utilities for dealing with Tensors.

Miscellaneous Utility Functions

```
tf.contrib.util.constant value(tensor)
```

Returns the constant value of the given tensor, if efficiently calculable.

This function attempts to partially evaluate the given tensor, and returns its value as a numpy ndarray if this succeeds.

TODO(<u>mrry</u>): Consider whether this function should use a registration mechanism like gradients and ShapeFunctions, so that it is easily extensible.

Args:

• tensor: The Tensor to be evaluated.

A numpy ndarray containing the constant value of the given tensor, or None if it cannot be calculated.

Raises:

• TypeError: if tensor is not an ops.Tensor.

```
tf.contrib.util.make_tensor_proto(values, dtype=None,
shape=None)
```

Create a TensorProto.

Args:

- values: Values to put in the TensorProto.
- dtype: Optional tensor_pb2 DataType value.
- shape: List of integers representing the dimensions of tensor.

Returns:

A TensorProto. Depending on the type, it may contain data in the "tensor_content" attribute, which is not directly useful to Python programs. To access the values you should convert the proto back to a numpy ndarray with tensor_util.MakeNdarray(proto).

Raises:

TypeError: if unsupported types are provided.

• ValueError: if arguments have inappropriate values.

make_tensor_proto accepts "values" of a python scalar, a python list, a numpy ndarray, or a numpy scalar.

If "values" is a python scalar or a python list, make_tensor_proto first convert it to numpy ndarray. If dtype is None, the conversion tries its best to infer the right numpy data type. Otherwise, the resulting numpy array has a compatible data type with the given dtype.

In either case above, the numpy ndarray (either the caller provided or the auto converted) must have the compatible type with dtype.

make_tensor_proto then converts the numpy array to a tensor proto.

If "shape" is None, the resulting tensor proto represents the numpy array precisely.

Otherwise, "shape" specifies the tensor's shape and the numpy array can not have more elements than what "shape" specifies.
